Bedrock Structure, Lithology and Ground Water:

Influences on Slope Failure Initiation

In Davis County, Utah

(December 1990)

Souren Nariman Ala

B.A., Princeton University

Chair of Advisory Committee: Dr. Christopher C. Mathewson

During May and June of 1983 and 1984, an unusually large number of land slips and debris flows occurred along the Wasatch Front, in north-central Utah. Failures on slopes underlain by rocks of the Precambrian Farmington Canyon Complex were often followed by new and sustained ground-water discharge. It has been proposed that elevated pore water pressures within the intensely fractured bedrock contribute to the initiation of slope failures.

In order to better understand the behavior of ground water in the mountain block, it was necessary to characterize the geological properties of the bedrock, and evaluate their influence on preferential ground-water flow paths. This investigation considers the roles of faults, lithological variations, fractures, fracture intersection lines and foliation planes in affecting the local and

regional hydrogeology.

The detailed geology of the Farmington Canyon Complex is extremely heterogeneous. Statistical and geological analyses of fractures, faults, foliation and lithologic variations reveal that spatial variability overrides any one factor contributing to the geometry of the structural fabric. However, inter-regional geological parameters such as lithology and proximity to faults do have an effect on the dispersion and orientation of fracture sets.

The overall fracture pattern in foliated rocks is resolved into a predictable form when variations in the orientation of foliation planes are removed. The resultant fracture geometry may indicate the direction of the greatest principal stress during the Sevier and Laramide orogenies.

The fractured bedrock constitutes an aquifer of highly variable properties. Analysis of stream discharge data suggests that a net northwestward flow of ground water is taking place along major structural lineaments. The distribution of ground-water discharge points is controlled by topography and by geological features including lithologic changes and/or low-angle fractures and foliation planes.

A comparison of slope aspects upon which slope failures have occurred indicates that slopes perpendicular to the main trend of faults (interpreted from aerial

photographs) experience the greatest number of slope failures. Neither fractures, fracture intersection lines nor foliation planes correlate systematically with these slopes.

This work is dedicated to  
Jeff, Julie, Jennifer and Laurie Keaton.

### ACKNOWLEDGEMENTS

I am indebted to a large number of people who helped me to complete this report. I am primarily grateful to my thesis committee: Dr. Christopher C. Mathewson gave me much support, and showed me the importance of synthesizing information; Dr. J. Richard Giardino helped me greatly in my data analysis; Dr. John H. Spang gave me valuable advice, especially with respect to the regional structural geology.

I am grateful to Dr. David V. Wiltchko for access to and help with the "Structure Graphics" program; Dr. Jeffrey R. Keaton for his expert help and encouragement; Dr. C. Brann Johnson for his teaching and insights; Dr. Dale F. Morgan for help in analyzing the results of the geophysical surveys. Ted Apotria's guidance in the field, and the excellent work and general example provided by Paul Santi were gratefully accepted.

Materials and expert advice were gladly received from Dr. Loren Anderson, Adolf Yonkee, Gary Christensen, Mike Lowe, Scott Williams and Sara Monteith. In addition, the United States Forest Service, Soil Conservation Service, and Davis County Planning Commission gave us information and materials. I also thank Dr. Bill Hicks, with the Forest Service in Oregon, for his input.

The Salt Lake City office of Dames and Moore generously provided for me to print the results of my

geophysical surveys. Mr. Roger Fallon of Salt Lake City did us a great service by flying us around the Wasatch Front canyons; much of the regional geological picture only became apparent after viewing photographs taken during that flight.

I thank the Keaton family for their hospitality. I am grateful to Kevin Coleman for his help and patience in the field, and for bringing out the the common ground shared by our complementary research efforts.

Lili Lyddon drafted almost all the figures in this report, with a masterful hand.

I thank the Utah Geological and Mineral Survey for their financial support (contract #89-0327). I thank the Center for Engineering Geosciences, Department of geology, Texas A&M University for funding, equipment, and moral support. I thank the Department of Geology, Texas A&M University, for funding the rental of the VLF geophysical tool.

I will be forever grateful for the love and support of my family: Ann, Fereydoun, Arjan, Tour and Natalyn.

## INTRODUCTION

Rapid population growth in the urban area along the eastern border of the Great Salt Lake, Utah, has led to residential development in the western foothills of the Wasatch Range (Figure 1). Such sites are conveniently located as well as being aesthetically attractive. However, much of this area is susceptible to debris flow and flood hazards. A large number of debris flows occurred on the Wasatch Front during May and June of 1983 and 1984. Although no lives were lost, there was significant damage to structures, and cumulative costs for the state ran in excess of 400 million dollars (Anderson et al., 1985).

Several studies have been conducted in the area since 1983, with the goal of defining the severity and extent of flood and debris flow hazards along the Wasatch Front (Pack, 1985; Brooks, 1986; Jadkowski, 1987; Keaton, 1988b; Monteith, 1988; Santi, 1988; Weiczorek et al., 1989; Mathewson et al., 1990). Attention has been focused on 1) identifying susceptible areas, 2) gaining a better understanding of failure mechanisms, and 3) determining the amount and velocity of sediment reaching the canyon mouth. This study is an attempt to clarify parts of categories 1 and 2, by considering the source of elevated

---

The style and format of this report follow that of  
The Bulletin of the Association of Engineering Geologists.

Figure 1. Location of the study area in the Wasatch Range, north central Utah. The 1500 m contour shows the elevation of the general slope gradient change at the base of the mountains. Numerous historical floods and debris flow sedimentation events have occurred at this elevation.

pore water pressures leading to slope failure. The main focus will be on characterizing the bedrock as a ground-water delivery system, by addressing the question "how and where do elevated pore water pressures develop?"

#### **Ground Water and Hillslope Processes**

Bedrock ground water is active in the evolution of hillslope landforms. Long term weathering of fractured metamorphic rocks under saturated conditions produces residual "saprolitic" soils which vary greatly in depth and composition (Figure 2). Differences in the resistance of the bedrock to weathering gradually become expressed in the topography, leading to the development of hollows on colluvial slopes. These in turn become loci for further weathering and accumulation of soil, debris and ground water (Reneau and Dietrich, 1987; Sidle, 1987). Areas of more highly fractured, weathered and thus, more permeable bedrock become sites of recurrent debris flow activity (Alger and Ellen, 1987; Tsukamoto and Minematsu, 1987).

#### **Slope Failure Mechanisms**

Failure of a slope takes place when the downslope component of applied shear stress overcomes the shear strength of the material (Chorley et al., 1984). Often, the slope is in a meta-stable condition, and failure is triggered by a sudden event. Possible examples are an increase in shear stress by added load from upslope, or a reduction in shear strength caused by removal of toe

**Figure 2.** Schematic cross-section of a typical soil profile in weathered metamorphic terrain (adapted from Deere and Patton, 1971).

support, seismic shock or most commonly, an increase in pore water pressure at the incipient failure surface.

Debris flows can be distinguished from block glides or slumps by their more fluid behavior, brought about by a greater water content. They are almost always preceded by extremely heavy rainfall or the melting of snow or frozen ground (Schuster and Krizek, 1978).

Antecedent rainfall of at least 25 cm followed by storms with an intensity of 0.6 cm/hr or greater initiated a series of damaging debris flows in the Santa Monica mountains of southern California (Campbell, 1975). These events took place in colluvial soils underlain by sedimentary, volcanic and low-grade metamorphic rocks ranging in age from Quaternary to Triassic (State of California Department of Natural Resources, 1954). The observed failure mechanism was a critical reduction of effective stress in the colluvium, due to an increase in pore water pressure. The pore water pressure increase was brought about by continued infiltration of surface water into saturated colluvium at a rate which exceeded the hydraulic conductivity of the underlying bedrock. A schematic diagram of this process is shown in Figure 3. Failures generally began as areally extensive blocks of colluvium, that subsequently disaggregated into flows (Campbell, 1975).

Tsukamoto and Minematsu (1987) have subdivided

Figure 3. Schematic diagram of a slope failure mechanism in which pore water pressure is increased through rapid infiltration of rainfall into saturated colluvial soil (adapted from Campbell, 1975).

hydrologic conditions leading to hillslope erosion according to the relative permeabilities of three shallow subsurface units: soil, "underlying soil", and weathered bedrock. When rainfall intensity greatly exceeds infiltration, surface erosion occurs. When infiltration greatly exceeds the permeability of the underlying soil, shallow slides take place. When the permeability of the underlying soil greatly exceeds that of the weathered bedrock, shallow to deep slides can occur (Tsukamoto and Minematsu, 1987).

An alternative mechanism to those discussed above involves the contribution of upwelling ground water from permeable zones in bedrock, rather than downward infiltration of water through the soil. If regional ground-water flow lines are projected onto a slope, the lower section of the slope is in a zone of discharge. Where low permeability rock units or clays prevent discharge, pore water pressure rises and the potential for slope failure is increased. Campbell (1975) notes that a bedrock source of ground water is generally associated with deep seated landslides rather than debris flows. However, upwelling ground water can cause piping in cohesionless soil (Deere and Patton, 1971), and this process has been recognized as a contributor to slurry flows (Howard and McLane, 1988).

Slope failures initiated by ground water from bedrock have hitherto also been associated with heavy rainfall. Eisenlohr (1952) correlated ground-water "blowouts" with layers of shattered rock recharged by rainfall on higher ground. Hack and Goodlett (1960) found "water blowouts" along the lower contact of an impermeable diabase sill within a hillside composed mainly of permeable clastic sedimentary rocks.

Everett (1979) observed that landslide sources on forested slopes in Mingo County, West Virginia were associated with the upper surfaces of relatively less permeable sandstones, interbedded with highly fractured coal beds. These events were, therefore, associated with perched rather than artesian water table conditions.

Evidence exists that artesian ground-water conditions helped initiate debris flows on slopes underlain by Precambrian metamorphic rocks of the Farmington Canyon Complex, Wasatch Front, Utah (Mathewson et al., 1990). In May and June of 1983 and 1984, the Wasatch Front was the site of numerous debris flows and floods. Many of these originated as small water blowouts which gathered material during their progress down the channel (Santi, 1988). Failures were not correlated with heavy rainfall, but with rapid spring snowmelt. Several debris flow scars experienced new discharge, which was sustained for up to six months after failure (Mathewson and Santi, 1987;

Mathewson et al., 1990).

Mathewson and Santi (1987) proposed that hydrostatic head in the fractured bedrock, combined with variations in topography, led to elevated pore water pressures in the axes of upper mountain swales. This hypothesis has been confirmed in at least one case: a study by Monteith (1988) showed that a landslide and debris flow in Steed Canyon (immediately south of Farmington Canyon) was initiated by artesian ground-water conditions.

Schematic diagrams of the mechanisms proposed by Mathewson and others (1990), Hack and Goodlett (1960), and Everett (1979) are shown in Figures 4 and 5. A third mechanism, observed by Hicks (1988) in the Cascade Mountains, Oregon, is shown in Figure 6.

A large number of landslides and debris flows have occurred in colluvial soils in hilly terrain overlying the highly fractured metamorphic Franciscan melange in Marin County, California. In a small test area in this region, Wilson and Dietrich (1987) were able to construct a contoured hydraulic conductivity profile along the axis of a hollow, using constant head permeability tests in more than 30 piezometer nests (Figure 7).

During a 25-year scale storm that occurred from February 12-20, 1986, water levels along the basin axis were monitored. Results implied that subsurface flow through bedrock was forced up to the surface at point B,

**Figure 4.** Schematic diagram of a slope failure mechanism in which ground water under significant hydrostatic pressure increases pore water pressures at the base of the soil profile. Communication to the surface is provided by low-angle fractures (adapted from Mathewson and Santi, 1987).

Figure 5. Schematic diagram of a slope failure mechanism in which pore water pressures in the soil are raised by perched and/or artesian ground-water conditions created by a relatively less permeable rock unit (based on concepts from Hack and Goodlett, 1960; and Everett, 1979).

Figure 6. Schematic diagram of a slope failure mechanism in which pore water pressures in the soil are raised by ground-water discharge via a relatively more permeable rock unit (after Hicks, 1988).

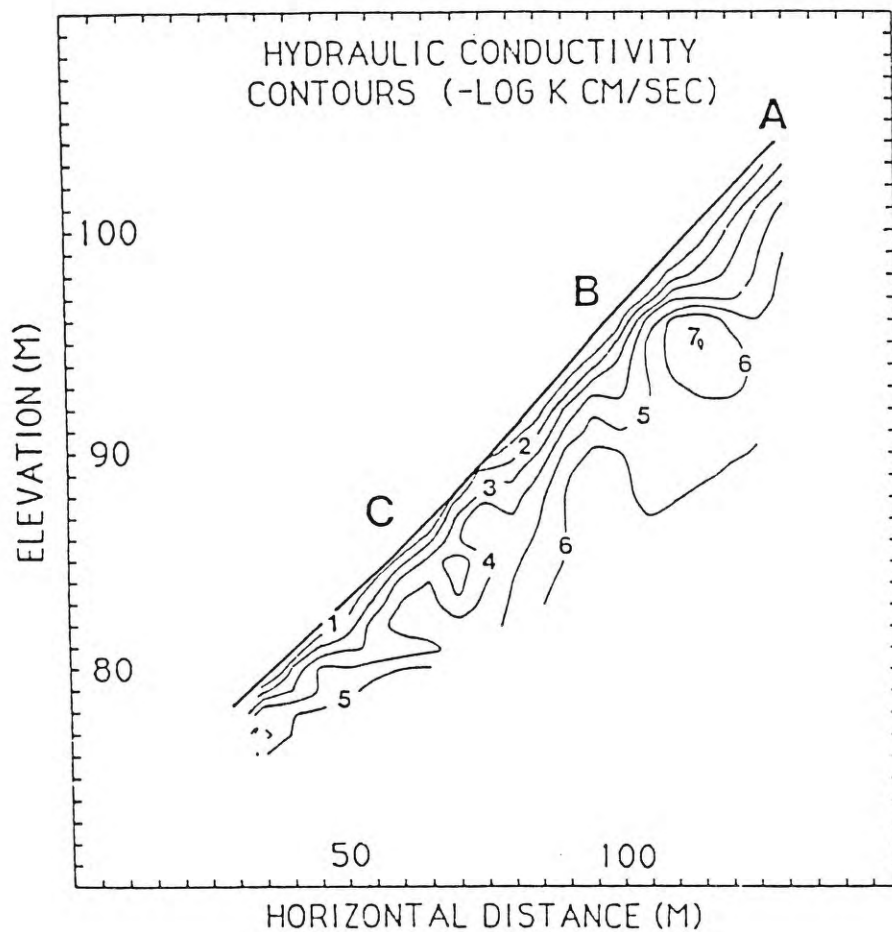

Figure 7. Location of piezometers in a study site in Marin County, CA (after Wilson and Dietrich, 1987).

at  $K=10^{-7}$  cm/sec, and was then able to drain back down at point C, at  $K=10^{-4}$  cm/sec (Figure 8). The authors concluded that permeability changes in bedrock may provide an important mechanism for debris flow initiation during periods of intense precipitation. The Franciscan formation, like the Farmington Canyon Complex, is highly fractured and lithologically heterogeneous.

The geology of the Farmington Canyon Complex undoubtedly affected the distribution of slope failures in this section of the Wasatch Front. Pack (1985) presents a multi-component model to predict landslide susceptibility in this area; he mentions that local geology is an important factor in determining landslide locations. However, he does not consider local geology in his model, declaring that bedrock variations are too site-specific for regional study. Olson (1985) states that, although an active ground-water system exists in this section of the Wasatch Front, the hydrogeology is poorly understood.

The slope failures of 1983 and 1984 in this section of the Wasatch Front have been correlated with an ancient uplifted erosional surface identified by Eardley (1944; cited in Vandre, 1985). Vandre (1985) shows that there is a relative increase in debris flow occurrences, as well as drainage heads, at the approximate elevation of the ancient surface. It is possible that this surface acts as a shelf, causing ponding and discharge of ground water

**Figure 8.** Contours of hydraulic conductivity in cross-sectional view along the axis of the Marin County study site. Contoured values are hydraulic conductivity, from  $10^{-1}$  to  $10^{-7}$  cm/sec (after Wilson and Dietrich, 1987).

to the surface. In addition, a relatively thicker soil profile (evident above the upper Rudd Creek failure scar) may have developed on top of the ancient surface. The role of this feature in the distribution of slope failure events was not analyzed in this study.

#### **Purpose of Study**

The purpose of this study was to test the hypothesis of Mathewson and Santi (1987) that elevated pore water pressure in colluvium is derived from ground water in the Farmington Canyon Complex. The objective then was to characterize the structure and lithology of the bedrock in terms of its ground-water storage and permeability characteristics.

## STUDY AREA

### Physiography

The study area is in Davis County, Utah, which includes a portion of the Wasatch Front, which comprises the western flank of the Wasatch Range, in north-central Utah. The western edge of the Front forms an approximate boundary between the uplifted Colorado plateau to the east and the extensional Basin and Range province to the west (Figure 9). The relief on the Wasatch Front is due to approximately 4 km of displacement on the Wasatch fault during the last 12 Ma (Naeser et al., 1983). A series of steep westward-draining canyons have eroded down into the mountain block.

The total relief on this part of the Wasatch Front is approximately 1200 m. Average annual precipitation increases 10 cm for every 200 m increase in elevation; above 2500 m, 90 percent of this is in the form of snow (Pankey and DeByle, 1984). The area is also subject to intense orographic rainstorms during the summer months.

The study area is located on rocks of the Farmington Canyon Complex, which is exposed east of the Wasatch Fault, and extends eastward to the highest ridge on the Front, beyond which it is buried by sediments of Paleozoic through Quaternary age (Figure 10). Although outcrops are common, the great majority of the land area is covered by

**Figure 9.** Davis County, Utah, is located in the zone dividing the Basin and Range province from the middle Rocky Mountains. The Farmington Canyon Complex outcrops in eastern Davis County.

Figure 10. Geologic map of the Precambrian Farmington Canyon Complex (simplified from Bryant, 1988).

vegetation, in the form of trees, scrub and grasses. The ridge crests, where much of the field data were gathered, have little or no vegetation or soil cover.

### Regional Geology

#### Petrology

The Farmington Canyon Complex consists of Precambrian metasediments which have experienced a long history of deformation and igneous intrusion. The dominant lithologies along the Wasatch Front between Bountiful and Ogden, Utah, consist of two generalized units. The first unit, "Afs", covering the southern portion of the Precambrian exposure, is made up of quartzofeldspathic gneiss, sillimanite-grade pelitic schist/gneiss, some quartzite, amphibolite lenses and numerous pegmatite dikes and sills. North of the town of Farmington, this unit grades into "Afm", a migmatite with interlayered and intergradational quartz monzonite gneiss, grey pelitic and quartzofeldspathic schist, greenish-black amphibolite, and pegmatite dikes (Bryant, 1988). Figure 10 shows the location of the gradational boundary between Afm and Afs. Within these two lithologic units are mapped several lenses of quartz monzonite gneiss (containing amphibolite lenses), quartzite, and amphibolite bodies. Localized zones of intensely sheared and mylonitized rocks are found at the base of the outcrop near the Wasatch Fault. Oval to highly elongate pegmatite dikes (quartz and microcline)

are abundant (Bryant, 1988). Figure 11 is a geologic map of the study area.

The oldest rocks in the Farmington Canyon Complex are the schists and gneisses. Detailed radiometric dating by Hashad and others (1970) and Hedge and others (1984) suggests the following events during the Precambrian era: Archean sandstones and shales were deposited between 3.0 and 3.6 Ga; a major igneous/metamorphic event occurred at 2.6 Ga, intruding and extruding gabbros and basalts. Another high temperature metamorphic episode took place at 1.8 Ga, which sheared and partly migmatized these rocks; at the same time they were intruded by quartz monzonite (Hedge et al., 1984). A late Precambrian or early Paleozoic metamorphism of lesser intensity was accompanied by local uplift at approximately 0.5 Ga.

#### **Structural History of the Region**

**Precambrian and Paleozoic:** The geologic evolution of this part of Utah includes periods of marine deposition, compression, intense volcanism and extension. Hintze (1982) divides the Phanerozoic in Utah into six phases, as seen in Figure 12. At the time of diagram 12I, the Farmington Canyon Complex was already in place, had experienced two episodes of intense metamorphism, and was either involved in, or was just emerging from, a lesser stage of metamorphism that generated the structural uplifts of the Northern Utah

# GEOLOGIC MAP OF UPPER PART OF STEED AND FORD CANYONS

**Figure 11.** Geologic map of the study area; developed from photogeology and field investigation. Star indicates position of a spring feeding Farmington Lake (see Figure 55).

Figure 12. Six phases of the geologic evolution of Utah. Note the importance of the northeast-trending "Paleozoic hinge line" in the development of the state (after Hintze, 1982).

Highland, (not shown in Figure 12) and the Uinta mountains.

The Paleozoic and early Mesozoic eras in this region were tectonically quiet, and consisted of shallow to intermediate marine deposition of clastics and carbonates. Sediment transport was westward from the craton until the Mississippian Antler Orogeny uplifted rocks to the west and reversed the direction of transport.

As shown by Young (1984), a number of large scale trends or "megalineaments" divide this region (Figure 13). Of particular interest is the junction of the Wasatch East and Uinta megalineaments, which can be traced to the location of the Cottonwood igneous stock. The Wasatch fault itself lies along the "Paleozoic hinge line", which is generally acknowledged to be the division between the late Precambrian through early Paleozoic uplifted craton and the miogeosyncline to the west, also known as the Wasatch line. This corresponds to the transition zone separating the Colorado Plateau and Rocky Mountain regions from the Basin and Range Province. The development of this trend as a major crustal boundary is evident in Figure 12.

The Northern Utah Highland, shown in Figure 14, includes the area around the outcropping Farmington Canyon Complex and its equivalent on Antelope Island. Eardley (1939) claims that early Paleozoic sediments up to 5,500 m

**Figure 13.** ERTS imagery showing major lineaments in the earth's crust in northeast Utah. Note the Wasatch East and Uintah megalineaments (shaded), mentioned in the text. The Wasatch Fault, which forms the western border of the Farmington Canyon Complex outcrop, lies along the Wasatch East Megalineament (adapted from Young, 1984).

Figure 14. The Northern Utah Highland distorted the geometry of thrust faults of the Sevier/Laramide orogenies (adapted from Tooker, 1983).

thick in adjacent basins pinched out completely on the flanks of this structure before Cretaceous (Laramide) age thrust-faulting began. According to Crittenden (1972), however, there was a considerable thickness of late Precambrian and early Cambrian sediments overlying the Northern Utah Highland, which were "tectonically stripped" by the Willard thrust sheet as it partially over-rode the structure. The thrust plate was being rapidly eroded synorogenically, and continued uplift of the Northern Utah Highland accelerated this process. In either interpretation, the Northern Utah Highland stood as a basement high at the start of Sevier/Laramide deformation.

**Mesozoic through early Cenozoic:** The Sevier/Laramide orogenies in the vicinity of the Wasatch Front consisted of eastward thrust-faulting of sediments, both broad and narrow-curvature folding, high angle reverse-faulting, normal faulting on the flanks of uplifts, and "transcurrent" strike-slip faulting through thrust sheets (Tooker, 1983). Eardley (1944) states that several stages of Sevier motion took place, resulting in a complex geometry of folds and thrust faults.

The main causes of asymmetry in the Sevier folds and thrusts west of the Wasatch front are the Precambrian autochthons. According to Eardley (1939), the Northern Utah Highland acted as a buttress in the way of the advancing thrust sheets, forcing them to wrap around it.

The westward face of the Northern Utah Highland was, therefore, an area of major stress concentration and realignment. Figure 15 shows the great influence of these uplifts, particularly the Northern Utah Highland, on the regional structure.

The concentration of stress on the rocks of the Farmington Canyon Complex from Sevier/Laramide deformation could be responsible for the dense network of faults in the northern half of Davis County, shown in Figure 10. It is possible that these faults are Precambrian features reactivated by the new stress regime. However, many of the early Precambrian faults and fractures are filled by pegmatite dikes with a different orientation to this fault network. The late Precambrian uplift may not have been strong enough to produce such faulting. It is likely, then, that a new fracture/fault network has been overprinted on the Precambrian structure, at least locally. A combination of compression during the Sevier orogeny, followed by a relaxation of compressive stress, may be the cause of the orthogonal fracture pattern in the rocks (Friedman, 1963).

**Miocene through Recent:** Faulting in the Basin and Range began about 12 Ma. Physiographically, the eastern margin of Basin and Range extension is represented by the Wasatch fault scarp. This fault trends approximately 12 degrees

Figure 15. Fold axes associated with Sevier/Laramide compression are distorted by the existing uplifts. FCC=Farmington Canyon Complex (adapted from Eardley, 1944).

west of north. It is locally discontinuous, and has an en echelon surface expression in the southern Wasatch Range (Eardley, 1939).

Investigators have generally had a difficult time interpreting seismic data from the Jordan and Sevier valleys (Zoback, 1983; Arabasz and Julander, 1986). They mention problems associated with complex subsurface structure and heterogeneous mechanical properties of rock units, multiple microseismic events within Range blocks rather than discrete events at block boundaries, and the disagreement of calculated earthquake slip vectors at depth with surface fault attitudes (Zoback, 1983; Arabasz and Julander, 1986). These phenomena are the result of structural constraints imposed by the complicated geologic development of the area, particularly the skewed fault and fold geometry created by Sevier thrusting around Precambrian autochthons.

Both Zoback (1983) and Arabasz and Julander (1986) characterize their study areas as complex transition zones between the Colorado Plateau and the Basin and Range provinces (Figure 16). Both document isolated occurrences of events generated by compressive stress and cases of strike-slip faulting.

Zoback (1983) mentions the low seismicity of the Farmington Canyon Complex relative to the adjacent basin and speculates that it is because of the greater competence of these rock units. It may also be due to the

**Figure 16.** Seismic slip vectors indicate a complex variety of stress orientations in the transition zone between the CP (Colorado Plateau) and the BR (Basin and Range) (after Arabasz and Julander, 1986).

deep fracture network in the bedrock, which allows it to adjust and compensate for applied stress.

The orientation of the least principal stress (the direction of crustal extension) in the Jordan Valley is along azimuth  $255^{\circ}$  (Zoback, 1983). In the Sevier valley, it is along azimuth  $282^{\circ}$  (Arabasz and Julander, 1986). The latter is in line with the Basin and Range as a whole. Zoback (1983) accounts for her data by offering two possibilities: that the relative rotation is due to compensation for ongoing spreading in the Rio Grande rift, or that it is a result of anisotropy imparted by the "late Precambrian rift margin", a reference to the Paleozoic hinge line discussed earlier.

## STATISTICAL ANALYSIS OF BEDROCK STRUCTURE IN THE STUDY AREA

The Farmington Canyon Complex has undergone multiple episodes of deformation, particularly by late Mesozoic through early Cenozoic age compression associated with the Sevier and Laramide orogenies. It is likely that Sevier and Laramide deformation has overprinted previous structures. The origin of this geologic structure has been discussed in the previous section. The function of this section is to characterize the present structural and lithologic configuration of the Farmington Canyon Complex.

A term commonly used to describe fractured rock masses is "complex". This term reveals nothing about the actual properties of the rock mass. It is hypothesized here that a comprehensive study of the "complex" structural fabric of bedrock can yield valuable information about its hydraulic properties and weathering characteristics. Thus, the main task of the following section is to further examine and refine the general phrase "complex structural fabric". "Structural fabric" here refers to photogeologically identified lineaments, macroscopic lithologic trends and the geometry of fractures and foliation viewed in the field. The study of the properties of these rock masses, individually and as groups, should produce a clearer and more detailed picture

of bedrock trends.

This section is a statistical characterization of the structural fabric of the Farmington Canyon Complex; its aim is to define similar structural domains within the study area. The next section correlates the regional view of lineaments obtained from photogeologic analysis with the detailed view of fracture geometries in the field, and attempts to interpret them geologically.

It is important to distinguish the statistical analysis in this section from the geological analysis in the next section. This section describes the dispersion of fracture orientations regardless of their actual orientation. In the next section, both the dispersion and the orientation of fracture sets are considered in their geological context.

Conclusions from these two sections are used in inferring potential ground-water flow paths in the bedrock, discussed in the section on hydrogeologic implications of the structural fabric.

#### **Data Acquisition**

Because the ultimate goal of this study is to better understand the hydrogeology of the bedrock in the study area, the properties chosen for study were those considered important in determining the hydraulic behavior of fractured rocks. In this study, no attempt has been made to arrive at quantitative values for bedrock

porosity, storativity, or hydraulic conductivity. Instead, a regional picture of hydrogeologic trends is developed.

There is a debate as to which geometric parameters among fracture orientation, length, spacing, aperture, surface roughness, density of interconnections, and/or other properties are the most important in determining hydraulic conductivity. According to Pollard and Aydin (1988), they are fracture spacing, orientation and aperture, and their connectivity, which is a function of the first two as well as fracture length. From a numerical simulation, Long and Witherspoon (1985) found that the degree of interconnectivity of fracture sets (a function of length and density) controls permeability, and that fracture length is more important than density in determining interconnectivity.

Of the categories of data mentioned above, orientation, length and spacing were readily obtainable in the field. The following physical features and their spatial distribution were studied: fracture orientation, length, spacing and aperture, and the orientation of major structural lineaments.

Once joint data have been gathered, how should they be analyzed? The appropriate probability distributions are not well known as yet (Baecher et al., 1977; Jones et al., 1985). At best, mathematical models of fractured

rock permeability can be summed up in the "Principle of Indeterminacy" (Leopold and Langbein, 1963; cited in Legrand, 1979, p. 344):

...the applicable physical laws may be satisfied by a large number of combinations of values of interdependent variables. As a result, a number of individual cases will differ among themselves, although their average is reproducible in different samples. Any individual case, then, cannot be forecast or specified except in a statistical sense. The result of an individual case is indeterminate.

Fracture and foliation orientations were gathered from 64 stations within the study area (Figure 17). A limited amount of fracture length and spacing data were also gathered. Stations where length and spacing information was obtained are also marked in Figure 17. Fracture apertures at the surface were approximated for a single outcrop in the study area, also shown in Figure 17.

#### **Avoiding Bias**

Bias in sampling fracture populations is almost inevitable, because outcrops are commonly two-dimensional, and fracture populations are not. There are many other sources of bias in the field sampling of fracture distributions and characteristics (Baecher et al., 1977; LaPointe and Hudson, 1985). In addition, the angle at which fractures intersect a free surface affects how the population will be represented; for instance, in aerial photography, steeply dipping fractures are more visible than flat-lying ones. The same is true at most physically

Figure 17. Stations where fracture orientation data were gathered are shown with dots. Diamonds show where fracture half-length and spacing data were taken. The star shows outcrop A98, where orientation, half-length, spacing and aperture data were taken along a scan line.

accessible outcrops. However, in the study area, many of the outcrops were found to have two or more exposed faces. In addition, fractures tended to be well exposed at the surface, allowing measurement of dip as well as strike. Figure 18 shows the distribution of outcrops in which more than one face is exposed.

Some of the sources of bias in the study area were:

- 1) the great majority of sampled outcrops were on ridges. Fractures perpendicular to the ridge trend are more likely to be encountered than those that parallel the ridge. Thus a regional bias is introduced.

- 2) Fractures are less likely to be filled with weathered material on the ridges than in the valleys.

- 3) In ground-level outcrops (see Figure 18) high angle fractures are more likely to be encountered than low-angle fractures.

Measures taken to obtain a truly representative sample were:

- 1) a large number of observations were made (over 1400 observations). At each outcrop, an effort was made to take a number of fractures from each visible set.

- 2) In the case of three-dimensional outcrops, which are common throughout the study area, orientation data were obtained from more than one exposed face of the outcrop. The majority of fracture dips appear to be steep. However, dip orientations for foliation planes are much less steep, within the same study area. This fact

Figure 18. Distribution of bedrock outcrops in the study area.

supports the contention that orientation data are relatively unbiased.

3) The lithology of the bedrock was noted for each fracture orientation.

4) Length and spacing data as well as orientation data were obtained using a scanline method in which only the trace lengths on one side of the tape are sampled. This method simplifies the mathematical estimation of the true (uncensored) trace length distribution from the raw (censored) data (Warburton, 1980). Although this conversion was not done for outcrops sampled in this study, the field technique itself was quicker and more suited to the irregular shape of outcrops in the study area. Thus, trace length data are presented as "half-lengths".

### **Plotting the Data**

Fracture analysis involving Fisher statistics and Kamb contouring, and presentation of stereonet and rose diagrams were carried out using the "Structure Graphics" program written by Wiltschko (1990).

### **Scatter Diagrams**

Initially, fracture orientations for each station and lithology were plotted on lower hemisphere Schmidt nets, in the form of scatter diagrams. Discrete joint sets are apparent in many of these diagrams, as in Figure 19 A. When orientation data for the same lithology for a number

of local outcrops are combined, joint sets are less clearly defined, as in Figure 19 B. If all the data for one locality are combined, orientations appear to be more or less randomly oriented, as in Figure 19 C.

This apparent randomness is actually the effect of mixing outcrops with different fracture sets into a single group. To avoid mixing different populations, principal fracture sets were determined, by eye, from the original data: one for each lithology within a single outcrop. These principal orientations were then ranked qualitatively as very good, good, fair, poor and very poor, depending on the visually determined tightness of each grouping; poor and very poor were not used. The remainder were compiled into a data set of "principal fracture orientations" for subsequent analysis.

#### **Random or Not?**

Both the "principal fracture orientations" data set and different groups of raw data were analyzed statistically to determine whether or not they were random, and also to further characterize their distributions. If the fracture orientation data recorded in the field were truly randomly distributed, then anisotropies in hydraulic properties of the bedrock must be attributed to other factors. Therefore the first step in characterizing fracture orientations was to establish whether any or all of the data sets were randomly

Figure 19. Scatter diagrams of fracture poles in Schmidt nets. A. Poles to fractures at one outcrop form discrete sets. B and C. No individual sets can be distinguished when the area of observation is increased.

oriented. Two methods were used to do this.

#### The Fisher Method

The first method was to view the poles to fracture planes as unit vectors in a sphere, and to compare the magnitude of the resultant vector,  $R$ , for each data set with that of  $R_0$ , a resultant vector calculated for random spherical distributions at 95 percent confidence (Tabulated by Irving, 1964, and included in Appendix 2). The magnitude of the resultant vector is calculated as follows:

$$R = S^2(l) + S^2(m) + S^2(n),$$

where  $S^2$  is the sum of squares of  $l$ ,  $m$  and  $n$ , which are the components of each of the three-dimensional vectors in a data set (Fisher, 1953, p. 296).

Fisher described the distribution of unit vectors in three-dimensional space with the probability density function  $P$ , where

$$P = [K/4(\pi) \sinh K] e^{K \cos \beta},$$

$\beta$  is the angular distance between a given point and the true population mean, and  $K$  is the precision parameter, discussed below (Tarling, 1983, p. 118). This equation has traditionally been most useful in paleomagnetic studies, where a spherical mean direction of remanent magnetism is sought among a distribution of orientations in an area. The mean is the resultant vector with the greatest magnitude of direction cosines.

This method is applicable to the analysis of fracture pole distributions. However, it must be used with caution when data sets are broadly distributed throughout the sphere, or when more than one fracture set is present. The majority of data sets from the study area fall into one or both of the above categories. Figure 20 shows how an inappropriate mean can be generated for a population of fractures.

#### Rotating Data

In order to overcome problems with broad distributions and/or multiple fracture sets, a technique similar to the one suggested by Andrews (1971) was used. The procedure involves finding the best-fit plane to all the poles in a data set; this divides the data set into roughly symmetrical halves. Then all the data points on one side of that plane are rotated by  $180^\circ$  about the vertical axis in the center of the hemisphere, and superimposed on the other half. This technique works best for distributions with two symmetrical fracture sets, which are common in outcrop data from the Farmington Canyon Complex; but it is applicable to all diffuse and disparate orientation distributions. An example from Andrews (1971) is shown in Figure 21.

Rotated data sets were analyzed by the Fisher method. Obviously, the rotated data are not truly representative either of the orientation or the grouping of the original

**Figure 20.** The Fisher mean pole of the data set of poles to fractures is labeled FP. A more accurate representation of the distribution of the data is  $P_1$ ,  $P_2$  and  $P_3$ , representing three separate poles.

**Figure 21. A.** An equatorial plot of bi-modal orientation data. **B.** The points on the left of the N-S line have been rotated by  $180^\circ$  and overlain on the right side. Open circles are the rotated points (after Andrews, 1971).

data sets. However, because the problem with disparate data is eliminated, the result is a better relative representation of the data sets, for purposes of comparison. Since the objective is simply to compare dispersion parameters for different data sets, the mathematical conversion between axial and vectorial data was deemed unnecessary. In addition, the rotated data sets are closer to spherical normal, which is required by the Fisher method. The statistical comparisons in this section use the rotated data sets.

The Fisher distribution is not entirely satisfactory for describing the orientation of poles to fractures, for two reasons: 1) it is a parametric method, which assumes that the data are grouped in a "spherical normal" array (Fisher, 1953), and 2) the Fisher distribution considers the dispersion of vectors on the entire surface of a sphere, where each vector is unidirectional. Fracture orientations are plotted as points on a lower hemisphere projection for convenience, and so may be characterized by Fisher statistics. However, they are really axes, which would be represented by two diametrically opposed points on the surface of an entire sphere (Mardia, 1972). Thus the dispersion of raw axial data cannot properly be analyzed using vectorial criteria (Mark, 1974; Yonkee, 1990).

In conclusion, it may not be advisable to use the Fisher method for 1) determining the randomness of groups of axial data, or 2) finding the trend and plunge of the spherical mean of widely dispersed or multi-modal pole orientations. However, it is believed that the Fisher method is useful for comparative purposes between data sets, particularly if the data are rotated.

#### The Eigenvalue Method

An alternative analytical method makes use of the eigenvalues of the orientation tensor calculated from the direction cosines of each data set (Woodcock and Naylor, 1983). These values are the magnitudes of the three axes of an ellipsoid that describes the shape of the distribution of orientations in the data set. The eigenvalues are normalized to the population of each data set, and the ratios between the greatest ( $S_1$ ), middle ( $S_2$ ) and least ( $S_3$ ) are compared. End members of ellipsoid shapes are elongate clusters, where  $S_1$  is much greater than  $S_2$  and  $S_3$ , and girdles, where  $S_1$  and  $S_2$  are similar, and  $S_3$  is much smaller (Woodcock and Naylor, 1983).

The other application of the eigenvalue technique is to test the randomness of groups of orientations. An ellipsoid that is not significantly different from a sphere cannot be described either as a cluster or a girdle. Woodcock and Naylor (1983) developed a statistic to test the "strength" of a group of orientations for

different confidence intervals, based on the ratio  $S_1/S_3$ .

Just as with the Fisher distribution, it is dangerous to use the eigenvalue method indiscriminately, particularly for data sets that have two or more preferred orientations. As shown in Figure 20, many of the data sets from the Farmington Canyon Complex are of this type.

### Comparisons of "Goodness of Fit"

The precision of a spherical distribution as described by Fisher (1953) is determined by two methods:

#### 1) The k parameter

This is an approximation of the true precision parameter K. K is 0 for completely uniform spherical distributions, and infinite for a single unit vector. K is a property of an entire population, so it cannot be known in a realistic field survey; but it can be approximated by the sample parameter k, which is given as

$$k=(n-1)/(n-R)$$

(Fisher, 1953, p. 303), where n is the sample population, and R is the magnitude of the resultant vector; thus the larger the value of k, the tighter the grouping. This relationship works for k greater than 3 and n greater than 7 (Tarling, 1983). If k is greater than 10, the calculated mean of a Fisher distribution of vectors is a good approximation of the true mean (Tarling, 1983). The maximum k for data sets from the Farmington Canyon Complex is 4.57, and most are well below this value. However, the

concern here is simply to characterize the dispersion of fracture orientations; the Fisher distribution is not used for analysis of the actual orientations of fracture sets in this study. Orientations have been determined by contouring the data, as discussed later in this section.

## 2) The radius of $\alpha_{95}$

This is a graphical way to compare spherical data. The radius of a circle on the surface of the unit sphere which contains 95 percent of the observations, centered on the resultant vector, is calculated (McElhinney, 1973). The smaller the radius, known as  $\alpha_{95}$ , the tighter the grouping.  $\alpha_{95}$  gives a good visual idea of groupings of fracture orientations about a mean value.

The two methods are similar in that they describe the closeness of the clustering of values around the mean vector. One difference between them is that  $k$  takes the entire sample into account, while  $\alpha_{95}$  disregards the "worst 5 percent" of the observations. This means that  $k$  is more susceptible to outliers than  $\alpha_{95}$ . It is not known which of the two parameters is most suitable for the description of fracture sets in a hydrogeological context.

## Results of Randomness and Goodness of Fit Analyses

### Randomness

#### 1) Fisher method

Table 1 shows that 71 percent of the unrotated fracture orientation data sets used in this analysis have

a ratio of  $R/R_o$  of greater than 1, indicating a non-random distribution at 95 percent confidence. For the remainder,  $R/R_o$  is less than 1, so they would seem to lack preferred orientation. These conclusions are not necessarily correct; certain distributions of points on a sphere are inappropriate for analysis using the Fisher method, as discussed above.

Table 1. Comparing values of  $R$  for each data set with  $R_o$  for an equivalent randomly oriented data set. Left column is for raw data; right column shows effect of rotation procedure (discussed above). Data sets marked by an asterisk (\*) are from principal fracture sets determined by eye from scatter diagrams of individual outcrops. XNFC and XNFD refer to fractures in outcrops adjacent to faults labeled C and D in Figure 11. 71 percent of the unrotated data sets are non-random at 95 percent confidence.

Data Set Name	Sample size (n)	R/R <sub>o</sub>	
		Unrotated	Rotated
*All Fracs	68	2.49	3.88
*Gneiss	49	1.80	3.39
*Amphibolite	33	2.11	2.62
*Pegmatite	21	1.24	2.03
XNFD	99	2.78	4.57
XNFC	82	2.17	4.19
*Region 1	10	0.83	1.45
*Region 2	9	1.14	1.46
*Region 3	20	1.41	2.04
*Region 4	15	1.19	1.93
*Region 5	10	0.99	1.74
*Region 6	10	0.99	1.62
*Region 7	10	0.93	1.38
*Region 8	13	1.16	1.62

Table 1 also compares unrotated and rotated  $R/R_o$  values for the data sets. All the rotated sets are non-

randomn at 95 percent confidence; but this result is also misleading, because values may be inflated above their "true" level. Nevertheless, although the value of  $R/R_o$  cannot prove that the remaining 29 percent of the original data sets are non-random, it provides a better description of the data. Eigenvalues were not calculated for the rotated data.

Fracture intersection lines were computed from the data in regions 1 through 8.  $R/R_o$  analysis for these (unrotated) data sets shows that they are all non-random at 95 percent confidence (see Table 2 below). A more complete explanation of the importance of fracture intersection lines is given further ahead.

**Table 2.**  $R/R_o$  values for fracture intersection lines in regions 1 through 8. The value for region 3 was not computed since the  $R_o$  value for  $n=190$  was not available.  $R_o$  for Reg4int was estimated from the tabulated value for  $n=100$ . All samples were computed from the "principal fracture orientations" data set. All are comfortably non-random at 95 percent confidence.

<u>Data Set Name</u>	<u>Sample Pop. (n)</u>	<u>R/R<sub>o</sub></u>
Reg1int	45	2.88
Reg2int	36	2.76
Reg3int	190	
Reg4int	105	3.51
Reg5int	45	2.32
Reg6int	45	2.15
Reg7int	45	2.35
Reg8int	78	2.63

## 2) Eigenvalue method

Figure 22 shows that poles to fracture sets for

Figure 22. A plot of the randomness of fracture pole orientation distributions at 90 and 95 percent confidence. Numbers 1 to 8 are for poles to fractures, by region. Numbers followed by "i" are for intersection lines, by region. C and D=data sets XNFC and XNFD. Gne=gneiss; Amp=amphibolite; Peg=pegmatite; All=entire study area; Bdg=foliations in study area. Region 2 has only 9 data points and would plot in the random field (adapted from Woodcock and Naylor, 1983).

regions 1 through 8 are random at 95 percent confidence. Therefore, at this confidence level, no preferred fracture orientations exist. However, at 90 percent confidence, regions 1 and 5 are non-random, indicating that these two data sets contain preferred orientations of fractures. The distribution of fractures adjacent to fault C is non-random at 95 percent confidence; fractures adjacent to fault D are non-random at 90 percent confidence (refer to the geologic map in Figure 11 for the location of faults C and D).

Poles to fractures in pegmatite and amphibolite are random, but in gneiss they are non-random; this is in agreement with the R/Ro analysis. Finally, the principal trends of fracture intersections for seven of the eight sub-regions plot well into the non-random field. This too is in agreement with the R/Ro analysis.

### **Statistical Comparisons**

#### **1) Fisher method**

An attempt was made to quantify differences in goodness of fit, or the "tightness" of groupings, for fracture sets within the study area, according to different geological criteria. These criteria were A) lithology, B) proximity to major lineaments, C) geomorphic (and perhaps structural) regions, D) different lithologies within geomorphic regions. Values of  $k$  and  $\alpha_{95}$  were computed for these criteria. The rotated data sets were

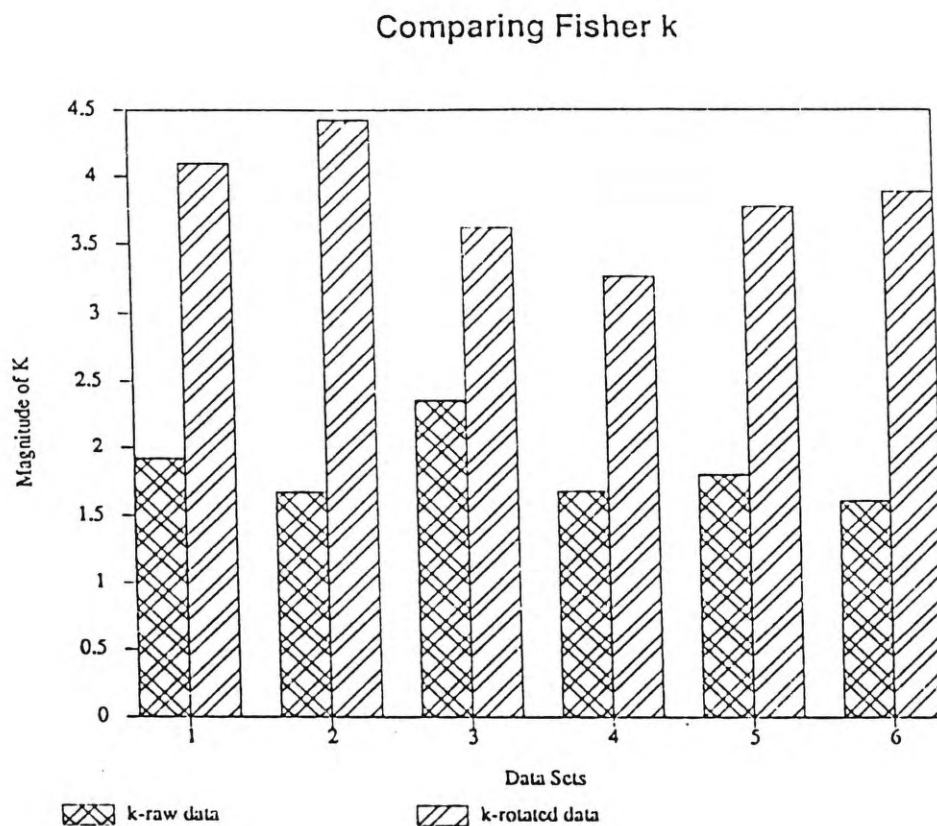

used for comparison. In cases A) and B) the raw data are plotted next to the rotated data for reference.

#### A) Lithology

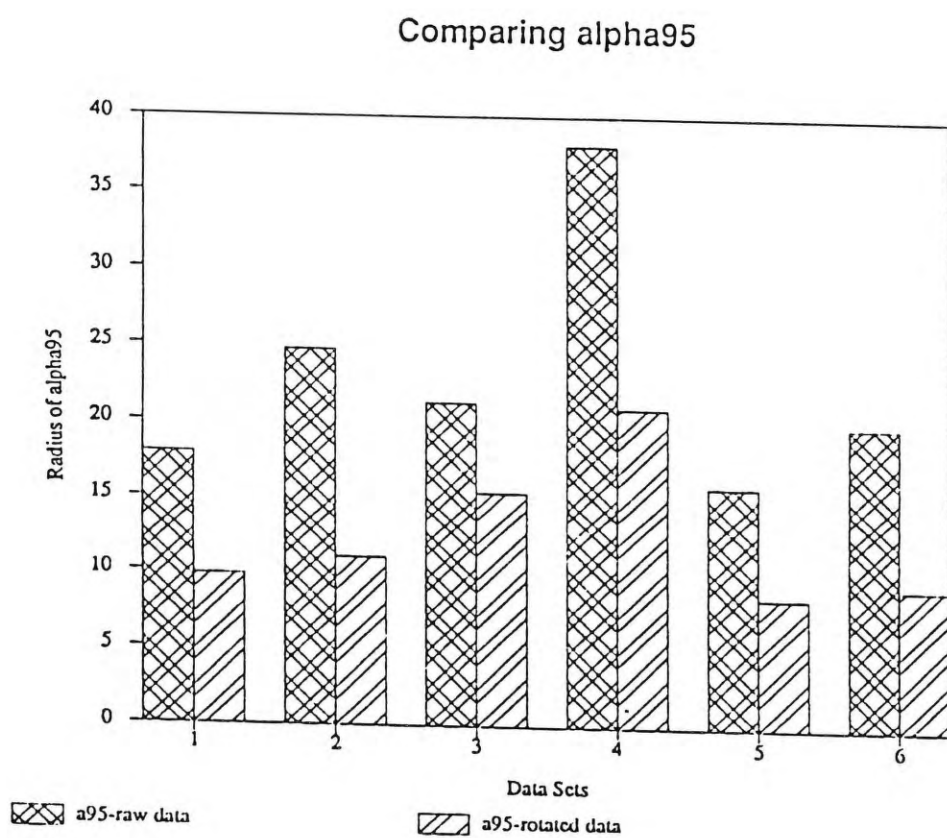

Variations in lithology have been simplified into gneiss, amphibolite and pegmatite, as shown in the geologic map in Figure 11. It was hypothesized that the foliated metamorphic rocks classified as gneiss should have more consistent fracture orientations than pegmatites. The results show that  $k$  is greatest for gneiss and least for pegmatite;  $\alpha_{95}$  is smallest for gneiss and greatest for pegmatite (Figures 23 and 24). The two parameters show that gneiss has the narrowest spread of fracture orientations, and pegmatite has the widest.

#### B) Proximity to major lineaments

At least three lineaments, interpreted to be faults, were mapped in the study area (Figure 11). It was hypothesized that the strain associated with faulting would have imposed a local disturbance on the regional fracture pattern. Figures 23 and 24 also show the statistical parameters for fracture orientations taken from outcrops adjacent to lineaments in the study area. The values of  $k$  and  $\alpha_{95}$  for these two data sets reflect values of  $k$  and  $\alpha_{95}$  for the entire study area. This implies that the distribution of orientations for sites adjacent to faults in the study area is not

**Figure 23.** Fisher k parameters compared for different data sets in the study area. 1=all fracture sets; 2=fracture sets in gneiss; 3=fracture sets in amphibolite; 4=fracture sets in pegmatite; 5=fracture sets adjacent to fault C; 6=fracture sets adjacent to fault D. The rotated k value is greatest for gneiss and least for pegmatite.

**Figure 24.** The rotated alpha95 value is smallest for gneiss (#2) and largest for pegmatite (#4).

significantly different from that of the "background", or entire study area.

#### C) Geomorphic regions

The field study area was divided into eight regions, corresponding to different geomorphic environments (Figure 25). Regions 1, 4, 5 and 6 are along sharp ridges forming the crest of the Wasatch Front; outcrops here are well exposed, and vegetation is sparse. Regions 2, 3 and 8 are located on less steep, wider, west-trending ridges between canyons; aspen and other trees and scrub are present here, and outcrops are less well exposed. Region 7 is on a steep south-facing slope. It was thought that fracturing on sharp ridges would be more consistently oriented than in the other regions.

The following paragraph is a review of results shown in Figures 26 and 27. The highest  $k$  values belong to regions 4, 5 and 6. The smallest values of  $\alpha_{95}$  are found in regions 3, 4, 5 and 6. Altogether, it appears that regions 4, 5 and 6 have the tightest grouping of fracture orientations. These correspond to three out of the four sharp ridges. Region 7 appears to be the most widely scattered, followed by region 2. The other regions have intermediate statistical properties.

#### D) Different lithologies within regions 1 through 8

The field data on fracture orientations included an identifier of location as well as lithology; this allowed

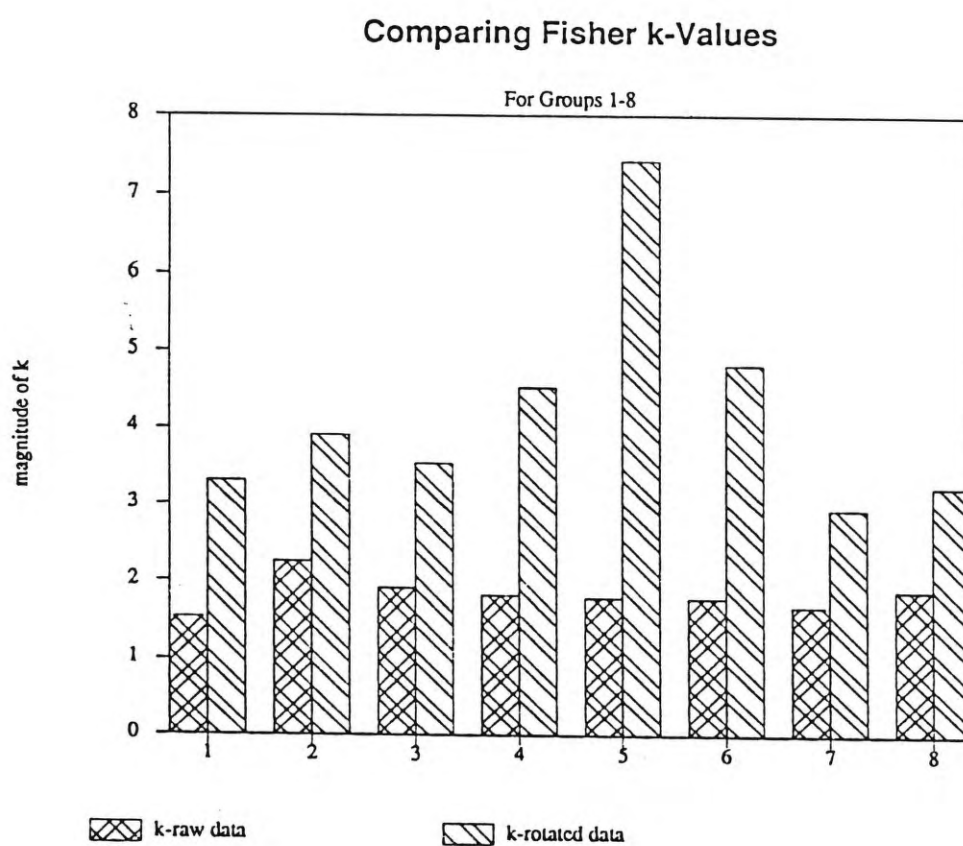

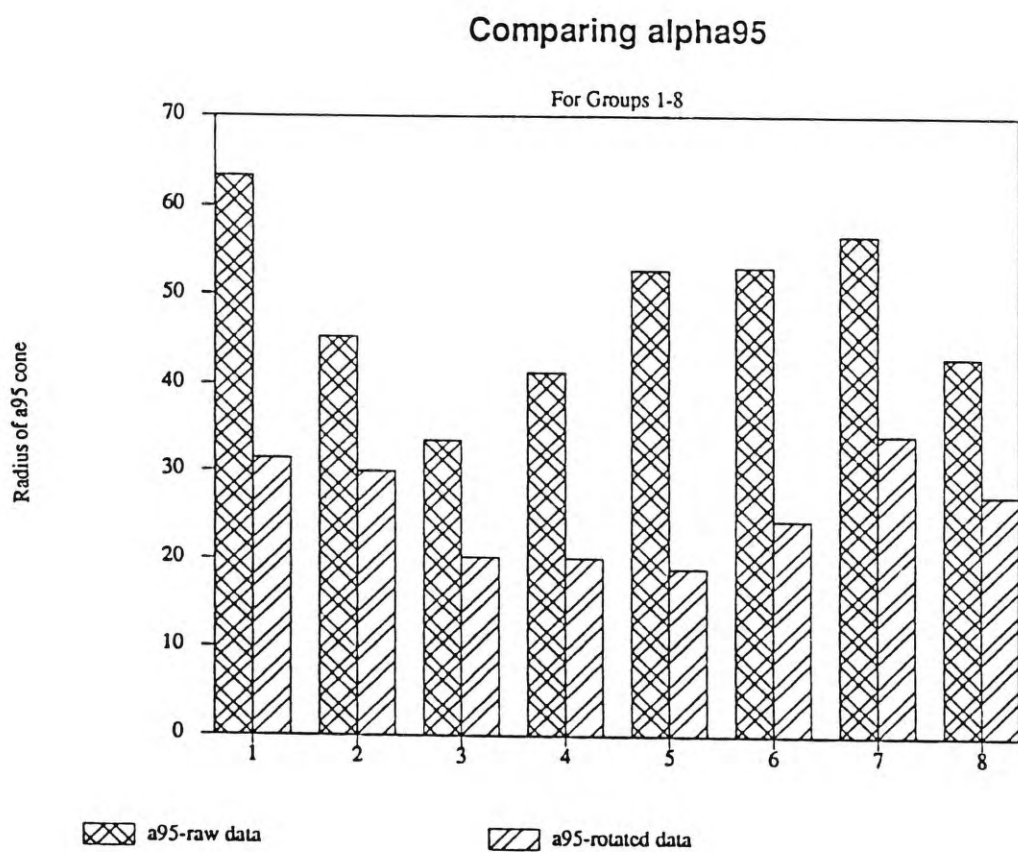

Figure 25. Regions 1 through 8, separated on the basis of geomorphic appearance. Fracture orientation data were classified by region.

**Figure 26.** The rotated k values are largest for regions 4, 5 and 6.

**Figure 27.** The rotated alpha95 values are smallest for regions 3, 4, 5 and 6.

the same data to be grouped in two different ways. The purpose of doing this was to see which criterion of lithology or spatial location had a greater influence on fracture orientation distribution. It was reasoned that if, for instance, sample parameters  $k$  and  $\alpha_{95}$  were not statistically different for different lithologies, then lithology in itself was not a significant influence on the distribution of fracture orientations.

The statistical test employed to compare the two groupings of sample parameters was the Kruskal-Wallis test. This is a nonparametric or "distribution-free" statistical test. It does not require that the sample be from a normal population (Davis, 1986). Nonparametric tests cannot be used for analyzing interval or ratio data, as can the sophisticated tests based on normal distributions (Conover, 1980). However, for this simple application, the Kruskal-Wallis test is adequate.

The original data were classified according to the two criteria;  $k$  and  $\alpha_{95}$  were calculated for each, forming two 3 by 8 matrices of 21 sample parameters (3 slots were empty due to a lack of data) as shown in Table 3. For each criterion, the null hypothesis stated that the given parameters were from the same population (i.e., not significantly different at 95 percent confidence).

Table 3. Descriptive parameters of fracture orientation distributions, grouped by lithology (rows) and by geomorphic region (columns).

Region	Lithology					
	Gneiss		Amphibolite		Pegmatite	
	k	95	k	95	k	95
1	6.32	11.4	5.06	10.4	4.81	8.8
2	3.44	22.0	2.99	13.8	3.22	10.3
3	-	-	3.68	10.1	3.15	9.6
4	4.12	8.2	4.45	24.5	4.05	8.7
5	3.62	11.6	4.83	15.8	-	-
6	4.26	8.5	4.84	15.1	4.07	17.6
7	3.46	11.8	3.14	18.9	-	-
8	4.92	8.1	4.06	11.6	6.19	40.2

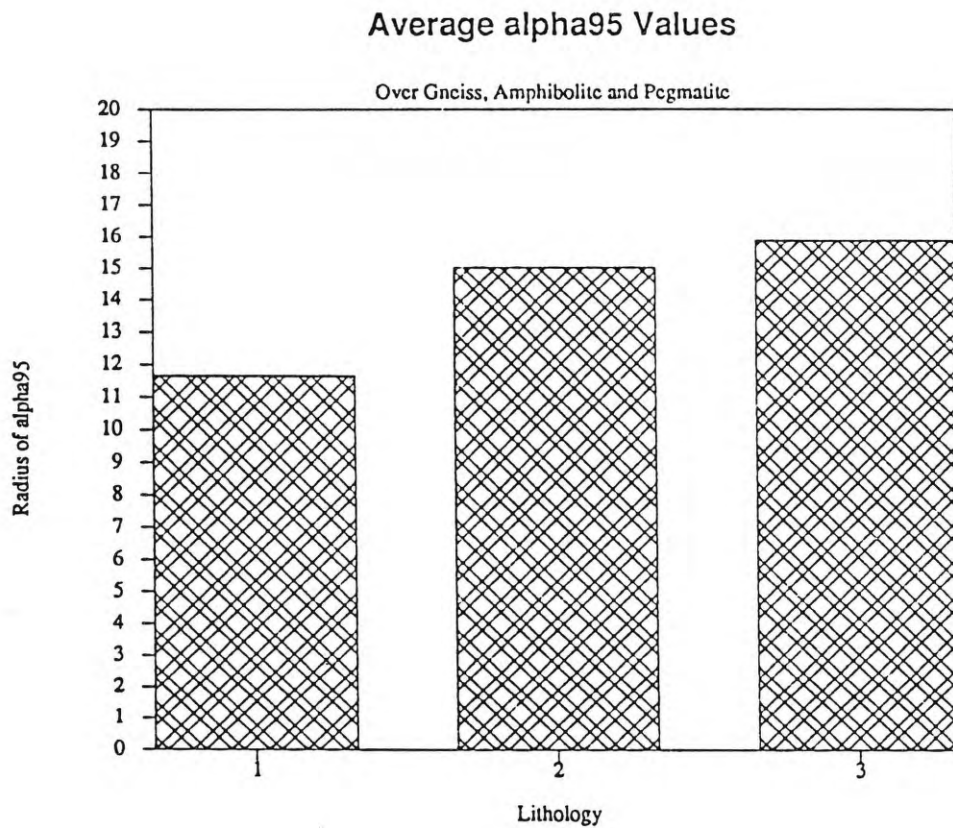

The Kruskal-Wallis test shows that k and alpha95 for gneiss, amphibolite and pegmatite are not significantly different at 95 percent confidence. None of the alpha95 values for regions 1 through 8 are significantly different either. However, one or more of the k values for regions 1 through 8 are different. This can be seen qualitatively in histograms of the parameters for different lithologies, and different regions (Figures 28 through 31).

It was mentioned above that the parameter k is more sensitive to data outliers than alpha95. This is probably the reason why the Kruskal-Wallis test showed significant differences in k for regions 1 through 8, but not for alpha95.

It is concluded that geomorphic environment is a more important influence on the distribution of fracture orientations than lithology. The test results, and the

**Figure 28.** Variability in k for gneiss (#1), amphibolite (#2), and pegmatite (#3). Average values range from near 4.0 to near 4.3.

**Figure 29.** Variability in alpha95 for the three lithologies. Average values range from near 11.5 to near 16.0.

**Figure 30.** Variability in k for regions 1 through 8. Average values range from near 3.0 to near 5.5.

**Figure 31.** Variability in alpha95 for regions 1 through 8. Average values range from near 10 to near 20.

steps involved in calculating the Kruskal-Wallis statistics are shown in Appendix 3.

An important assumption in this test is that the two criteria (lithology and geomorphic region) are independent (Milton and Arnold, 1986). It is likely that there is a geological link between the distribution of lithologies and the geomorphic character of regions; for example, the sharp ridges are in many cases the site of elongate pegmatite outcrops. However, for the Kruskal-Wallis tests, the assumption of independence was justified, because statistical comparisons were made within each classification of variables. In other words, lithology was analyzed separately from regions.

## 2) Eigenvalue method

The normalized eigenvalue ratios of each data set were compared to show the general shape of the distributions (i.e. towards clusters or girdles). Figure 32 shows how the shapes of the fracture pole orientations can be described by the relative magnitudes of  $S_1$ ,  $S_2$  and  $S_3$ . The data sets for the Farmington Canyon Complex are shown in Figure 33. In the perspective offered by Figure 32, most of these data have "weak" fabric strength. Few of the groupings represent either clusters or girdles. The only obvious girdles are for Bdg (the set of foliations) and the fractures in region 2. Relatively strong clusters are seen for fracture intersection lines

Figure 32. A Plot of ellipsoid shapes described by the relative lengths of their axes, as indicated by the relative magnitudes of the normalized eigenvalues  $S_1$ ,  $S_2$  and  $S_3$ .  $C$  is a measure of departure from sphericity of the ellipsoid; data at the origin are spheres (after Woodcock and Naylor, 1983).

Figure 33. Eigenvalue ratio plot showing the shape of fracture orientation sets from the Farmington Canyon Complex. Dots are poles to fractures; squares are intersection lines; abbreviations are the same as for Figure 22 (adapted from Woodcock and Naylor, 1983.)

in region 2, and for fractures in pegmatite.

An interesting observation from Figure 33 is that poles to fractures plot opposite to fracture intersection lines generated from the same data set. Thus, a well-defined girdle configuration of fracture orientations will have a tight cluster of intersection lines.

### Summary and Discussion of Results

The R/Ro analysis of unrotated data suggests that at least 71 percent of the fracture orientation distribution samples selected from the field data in the study area are non-random at a 95 percent confidence level. These findings are incompatible with the results of the eigenvalue tests for the same data sets (Figure 22), which finds them all to be random at 95 percent, except gneiss and data set XNFC. In addition, at 90 percent confidence, regions 1 and 5 and data set XNFD are non-random.

In view of the limitations of the Fisher method (discussed above), the results from the eigenvalue analysis are accepted: 1) there are no preferred orientations in principal fracture sets for the entire study area, for pegmatites or amphibolites, or for any of the eight sub-regions of the study area at 95 percent confidence, and 2) contrary to the Fisher analysis results, it appears that there is a significant difference (at 90 percent confidence) between the dispersion of fractures adjacent to faults and those of the

"background", or entire study area.

Among rotated data sets analyzed by the Fisher method, the most tightly focused fracture orientation groups were found in gneiss, and in regions 4, 5 and 6. This agrees to some extent with the eigenvalue analysis of unrotated data sets, which found fractures in gneiss, and in regions 1 and 5, to be non-random at 90 percent confidence. Both the R/Ro and eigenvalue tests on (unrotated) fracture intersection lines for regions 1 through 8 indicate non-randomness at 95 percent confidence, except for region 7, which is random according to the eigenvalue analysis.

The fact that the majority of data sets of fracture intersections are non-random suggests that a preferred orientation of the structural fabric does exist, which is not apparent in the analyses of the fractures themselves. This implies that fracture sets are not truly randomly oriented, and that neither the Fisher nor the eigenvalue analyses are completely satisfactory for such complex and poorly focused orientation data. The Kamb contouring method (discussed ahead) also supports the idea that there are preferred orientations of fractures in these data sets.

The Kruskal-Wallis test on the dispersion parameter  $k$  shows that variations in fracturing style between lithologies are overshadowed by the variation between

geomorphic environments. However, it is important to recognize that the differences between these regions are the result of geological processes of various types. More resistant lithologies exist along ridges (regions 1, 4, 5 and 6). Regions 2, 3 and 8 are cut by faults; Bryant (1988, p. 43) notes the sites of high-angle faults are wide zones of thicker soil development, "marked by gullies, notches, and vegetation", as shown in Figure 34. The areas depicted in this figure have a similar geomorphic appearance to regions 2, 3 and 8.

These results bring out the truly heterogeneous geological nature of this part of the Farmington Canyon Complex, consistent with its complex geologic history. It is also seen that care must be taken in applying statistical analyses to real geological data, in order to obtain meaningful results. A further implication for this area is that detailed analyses over the entire study area, or within small blocks of the study area, may be less useful than analyses that determine the size and extent of more or less homogeneous regions, such as photogeologic investigation.

#### **Contouring Preferred Orientations**

Having statistically characterized the data in terms of randomness and precision, a method was sought which would display the orientation as well as the dispersion of fracture sets. This was accomplished by contouring

**Figure 34.** Geomorphic expression of two high-angle faults in the Farmington Canyon Complex. A. Francis Peak Fault B. A fault near Bountiful Peak (after Bryant, 1988).

observations by their density on the lower surface of a hemisphere stereonet.

Contouring the orientations of poles to fracture planes clearly identifies fracture sets. Commonly, poles to fractures are contoured by the number of observations within a specified percentage of the area of the hemisphere. This method can be inconclusive for large data sets, because, as the number of poles to be contoured increases, their density increases throughout the hemisphere, and much "noise" may be generated.

The contouring procedure used in this analysis was developed by W.B. Kamb (1959). The Kamb method works independently of the number of observations in the data set. A counting area "A" is assigned such that the number of observations "E" falling within A is equal to 3 times the standard deviation of  $n$ , the number of points that will fall within A if the sampling is random (i.e., no preferred orientations). The reason that  $3\sigma$  is chosen as the lower threshold of significant non-randomness is that randomly oriented groupings of fractures may coincidentally contain points in close proximity to each other, thus imitating a non-random grouping. Raising the requirement for non-randomness allows for this problem. For a population of vectors on a sphere, with no preferred orientation, the following equation can be written (Kamb, 1959, Appendix):

$$\sigma/E = ([1-A]/nA)^{1/2}, \text{ where } E=nA.$$

Contours were drawn to separate densities up to  $3\sigma$ , above  $3\sigma$  to  $5\sigma$ , above  $5\sigma$  to  $7\sigma$ , and so on. Kamb contours of the data sets described in the previous section are shown in the next section.

### **Orientations of Fracture Intersections**

The degree of interconnection of fractures has a great effect on fluid flow through fractured rocks (Long and Witherspoon, 1985). Fracture connectivity is not simple but depends on fracture orientation, length and density.

It has already been shown that samples of fracture intersection lines computed from fractures in regions 1 through 8 of the study area are clearly non-randomly distributed, except for region 7. The Structure Graphics program (Wiltschko, 1990) calculates and plots the orientations of all possible lines of intersection between planes in a data set, assuming fractures are infinite planes. This is an important assumption, and may be unreasonable as a basis for computing hydraulic permeability if the fracture length and density of a sample are non-uniform; if this is the case, longer, more closely spaced fractures will be better connected than shorter, more widely spaced ones, which might greatly affect the main permeability trends (Long and Witherspoon, 1985).

A scan-line survey of one outcrop in the region (Station 98) revealed the following information about the orientations of fractures of different lengths and apertures:

1) Longer fractures were oriented similarly to the complete data set (Figures 35 A and B).

2) Open fractures were oriented similarly to the complete data set (Figure 35 C).

If outcrop A98 is representative of the region, the three-dimensional structure of shallow bedrock fractures is relatively uniform for fractures of different lengths and apertures. Other outcrops were qualitatively observed to have similar properties. This analysis helps justify the method used for calculating fracture intersection lines, because if fractures of different types are similarly oriented, their intersection line (and relative permeability) trends should also be similar.

#### Fracture Spacing and Length

Fracture spacing and length data were collected for a few of the stations, as shown in Figure 17. The data collection technique has already been described. In each case, the scan line was oriented as near as possible to perpendicular to the principal fracture set. Fracture half-lengths, and the spacing between them, were recorded. In some cases, fractures extended to the edges of outcrops. The lengths of these fractures are not known,

**Figure 35.** Contoured Schmidt nets of poles to fractures at outcrop A98. A. All fractures B. Fractures with half-lengths greater than 80 mm C. Fractures with apertures greater than approximately 0.5 mm.

but the observed lengths were used in subsequent analyses. The irregular surface and elongate shape of most of the outcrops limited the utility of fracture length information.

Results are similar for most stations. Examples are presented, for three different lithologies, in Figures 36, 37 and 38. Both length and spacing data are exponentially or lognormally distributed: most of the fractures are short and closely spaced. There is a lack of longer, more widely spaced fractures. The same distribution was found at almost all outcrops, regardless of lithology. It is not clear what these distributions imply for the hydrogeologic behavior of the rock mass.

**Figure 36.** Fracture spacing and half-length for a gneiss outcrop (scan line technique).

**Figure 37.** Fracture spacing and half-length for an amphibolite outcrop (scan line technique).

**Figure 38.** Fracture spacing and half-length for a pegmatite outcrop (scan line technique).

## GEOLOGIC INTERPRETATION OF THE STRUCTURAL FABRIC

## Orientations of Fractures and Foliation

## Entire Study Area

The principal pole(s) for each outcrop were contoured in one diagram for the entire study area (Figure 39). The density of poles is a maximum of  $7\sigma$ . There are two clusters of poles, as shown in Table 4. The strike of the most pervasive set of fracture planes is approximately  $57^\circ$  from the trend of major faults in this area (shown as dashed lines in Figure 11), and  $65^\circ$  from the orientation of the Wasatch Fault. (Structural trends are given in azimuth angle from true north, generally between  $180^\circ$  and  $359^\circ$ ). The average dip for this set is  $79^\circ$  SE.

Table 4. Mean orientations of the principal fracture and foliation sets estimated from Figures 39 and 40 A.

Data Set	Poles	Planes
	Trend/Plunge	Strike/dip
All Fractures	$323^\circ/11^\circ$	$233^\circ/79^\circ$ SE
	$196^\circ/40^\circ$	$286^\circ/50^\circ$ N
All Foliations	$221^\circ/57^\circ$	$311^\circ/33^\circ$ SW

Figure 40 A shows Kamb contours of poles to observable foliation planes within the study area. The orientation of the greatest density of poles to foliations is listed in Table 4. The poles form a girdle configuration about a pole located at  $291^\circ$ ,  $20^\circ$ . This distribution agrees well with similar data obtained by

## ALL PRINCIPAL FRACTURE SETS

Figure 39. Contoured Schmidt net of poles to fracture sets for the entire study area.

**Figure 40** A. Contoured Schmidt net (Kamb method) of poles to all foliations in the study area, showing a girdle around a pole at azimuth  $291^\circ$ , dip  $20^\circ$ . B. Contoured poles to foliation for non-cataclastic rocks in Bountiful Peak quadrangle form a girdle around a pole at azimuth  $303^\circ$ , dip  $10^\circ$  (after Bryant, 1988). Contours in this diagram are for pole density percent (0.65, 2, 3.3, 4.5 and 6 percent) within a fixed area of the sphere (1 percent).

Bryant (1988), shown in Figure 40 B. Comparing Figure 40 A with Figure 39, it is apparent that the principal set of poles to fractures and the greatest density of poles to foliation planes are very nearly orthogonal in three dimensions.

**Lithologic control:** Rocks of different lithologies have different moduli and will fracture in different ways. Lithologic control of fracture orientations accounts for some of the variability in orientations in Figure 39. Figures 41 A, B and C show these differences graphically. Table 5 lists the orientations of the principal fracture sets for each lithology. Note that the contoured poles for pegmatite outcrops are distinctly different from the other two.

**Table 5.** Mean orientations of the principal fracture sets estimated from Figure 41 A, B and C. Data sets are from principal fracture sets estimated by eye from scatter diagrams for individual outcrops.

Data Set	Poles	Planes
	Trend/Plunge	Strike/Dip
Gneiss	178°/21°	268°/69°N
	307°/29°	217°/61°SE
	330°/5°	240°/85°SE
Amphibolite	309°/20°	219°/70°SE
Pegmatite	3°/8°	273°/82°S
	197°/9°	287°/81°N

The similarity of amphibolite and gneiss fracture orientations implies a similar geologic and structural history for these lithologies, in contrast to the pattern

**Figure 41.** Contoured poles to principal fracture sets over the entire study area for different lithologies: A=gneiss; B=amphibolite; C=pegmatite.

observed in pegmatite outcrops. This is what would be expected, given the lithologic and genetic similarity of the amphibolite and felsic gneisses, and their dissimilarity with pegmatite (Bryant, 1988). The different engineering properties of pegmatite are also significant, in that they must have produced local changes in stress distribution during structural deformation.

Rotating fracture orientations: The above analyses are useful in determining an overall picture of fracture set orientations in the study area. However, from the evidence presented in the previous section, it could be argued that any "global" method of characterizing fracture orientations in this part of the Farmington Canyon Complex misrepresents the data because it does not take spatial variability into account.

Geological controls on the regional variability of fracture orientations were discussed to some extent in the previous section. The geological evolution of structures in the Farmington Canyon Complex has also been discussed, in a regional context. Unfortunately, the very complicated geology of the Farmington Canyon Complex makes it difficult to identify regionally consistent structures within the study area. Differences in rock strengths and pre-existing structures have complicated subsequent patterns of deformation.

In the study area, no coherent pattern of folding is apparent; however, the majority of the metamorphic rocks are foliated. Foliation is a regionally consistent characteristic of rocks, in that it may indicate the direction of the greatest principal stress during metamorphism. Bryant (1988) suggests that foliation follows the general pattern of folding within the Farmington Canyon Complex, though both are locally contorted. With this in mind, it was considered that "unfolding" the folded foliation would reveal a regionally pervasive structural fabric.

To allow for regional variability, it was assumed that all foliation planes were originally parallel and horizontal. Differences in foliation orientations were removed so that all fractures were oriented relative to horizontal foliation planes. The unfolding procedure used the fact that most outcrops contained both fractures and well-defined foliation planes. The principal pole(s) to foliation for a given outcrop were determined. If more than one set of foliation planes existed, that outcrop was not used. The pole was rotated to vertical (to bring the principal foliation plane to horizontal). Fractures from that outcrop were then rotated by the same amount.

Rotated and unrotated fractures are compared for the entire study area (Figures 42 A and B) and for different lithologies within the entire study area (Figures 43 and

**Figure 42.** Contoured poles to fractures for all outcrops that included foliation as well as fracture data. A. Before rotation to a common horizontal foliation plane B. After rotation. A, B<sub>1</sub>, B<sub>2</sub>, C<sub>1</sub> and C<sub>2</sub> are zones of high pole density referred to in the text, and in Figure 45.

Figure 43. Contoured poles to fractures for gneiss outcrops. A. Before rotation to a common horizontal foliation plane B. After rotation.

44, A and B). Although the general spread of fracture orientations showed very little change, some differences can be seen between unrotated and rotated data sets. It appears that fracture dips are steeper overall, and perpendicular to foliation. This is to be expected if fractures post-date foliation; fractures form early in the lithification history of sedimentary rocks, and are commonly perpendicular to bedding (Nickelsen, 1974; Hodgson, 1961). Mechanically, the relationship of fractures to foliation bands in rocks of the Farmington Canyon Complex appears to be similar to that of fractures in layered sedimentary rocks.

The data set containing all the rotated fractures (Figure 42 B) shows an interesting grouping around the perimeter of the stereonet. There are two areas of high fracture pole density,  $76^\circ$  apart ( $B_1$  and  $B_2$ ), approximately bisected by a third group of poles. This central group of poles (A) corresponds to a group of fracture planes striking along azimuth  $211^\circ$  and dipping  $75^\circ$  northwest.

According to Friedman (1963), the maximum principal compressive stress for rock deformation is oriented parallel to a plane bisecting shear planes which are generally  $60^\circ$  apart (Figure 45). In addition, a fourth fracture develops orthogonal to the greatest principal stress if any relaxation of compression occurs (Friedman,

**Figure 44.** Contoured poles to fractures for amphibolite outcrops. A. Before rotation to a common horizontal foliation plane B. After rotation.

**Figure 45.** Fractures forming under applied stress. A is parallel to the greatest principal compressive stress. B<sub>1</sub> and B<sub>2</sub> are shear planes 60° apart, bisected by A. C is orthogonal to A, and is a relaxation feature (after Friedman, 1963).

1963).

This model appears to have been reproduced in Figure 42 B. Two less well defined sets of poles to fracture planes are shown in this figure (poles are labelled as  $C_1$  and  $C_2$ : fracture set orientations are  $294^\circ$ ,  $63^\circ$  SW and  $298^\circ$ ,  $71^\circ$  NE) whose orientations fit this model. If foliation planes were approximately horizontal at the onset of regional compression, then the rotated fracture pattern in the metasedimentary rocks of the study area may be associated with regional stresses leading up to the Sevier and Laramide orogenies. Similar patterns have been observed in structural forelands by Engelder (1982), Engelder and Geiser (1980) and Babcock (1973). In the Farmington Canyon Complex, such a pattern may subsequently have been broken up by folding and faulting associated with intense deformation during the Laramide orogeny.

If the idea of shear planes is ignored, figure 42 B can be interpreted differently: the planes corresponding to  $C_1$  and  $C_2$  could represent the orientation of the greatest principal stress during Sevier/Laramide compression, and the set of planes corresponding to A could be relaxation fractures which developed after the end of compression. This is more consistent with the estimated southeasterly trajectory of compression during the Sevier orogeny (Hollet et al., 1978).

### **Influence of Faults**

Fracture and foliation orientations at outcrops were also grouped according to their position with respect to mapped faults. The analyses in the previous section showed that fractures in outcrops adjacent to faults are non-randomly oriented at 95 percent confidence. For the two faults considered, the contoured hemisphere plots (Figures 46 A and B) are very similar to the overall orientation of fractures shown in Figure 39.

### **Mapping Fracture Data**

Another way to account for spatial variability is to map the data. The spatial distribution of rock types and faults within the study area is shown in Figure 11. This geologic map shows observed and inferred outcrop patterns, lithologies, and best estimates of strike and dip, taken from foliated gneisses and interbedded gneiss and pegmatite. The variety of lithologies has been generalized into amphibolite, pegmatite, and gneissic rocks (generally felsic gneiss).

The strikes of principal fracture sets for the entire study area, presented (as poles) in stereonet form in Figure 39, are shown in Figure 47. Only the strikes are shown here for simplicity; this is justified because the majority of fracture dips are relatively uniform and steep. This figure illustrates the fact that the majority of sampled fractures are roughly perpendicular to the

**Figure 46.** Contoured poles to fractures adjacent to faults in the study area. **A.** Data set XNFC, corresponding to the fault labeled C in Figure 11. **B.** Data set XNFD, corresponding to the fault labeled D in Figure 11.

summit ridge. It is not known how much of this pattern is the result of sampling bias.

Figure 48 shows the orientations of fracture intersection lines calculated from the "principal orientations" data set, for geomorphic regions 1 through 8. The spread of orientations is generally smaller for intersection lines than for the fracture planes themselves, with the exception of region 7. The overall trend is northeasterly, as shown in Figure 49; but there are local exceptions, such as in regions 3 and 4, where two of the three principal trends are sub-parallel to a fault running through the area. In region 7, several diffuse trends exist; they coincide with more intense faulting in that locality. Because of this inconsistency, it is not clear exactly what geometric relationship exists between the orientation of fracture intersections and the trend of faults.

#### **Aerial Photograph Analysis**

Stereoscopic aerial photographs at 1:12000 scale, taken in 1980 and 1981, were used to develop a rose diagram of all visible surface lineaments in the study area (Figure 50). These lineaments trend most strongly toward azimuths 185°, 295° and 355°. The generally north-trending group is sub-parallel to the Wasatch Fault; the other is oriented northwest, approximately 60° from the first.

Figure 47. Strikes of the principal fracture sets in the study area.

Figure 48. Trend and plunge of the principal sets of fracture intersection lines for regions 1 through 8.

Figure 49. Rose diagram of the trends of intersection lines mapped in Figure 48.

Figure 50. Rose diagram of all structural lineaments in the study area visible in stereoscopic color aerial photographs at 1:12000 scale.

The structural lineament groupings correspond well with the principal trends (approximately  $180^{\circ}$  and  $290^{\circ}$ ) of large-scale faults in the study area. These were taken from Bryant (1988), and also independently interpreted from 1946 1:20000-scale black and white aerial photographs; some sections were checked in the field. They are shown as dashed lines in Figure 11. The trends of these two groups of lineaments are perpendicular and oblique to the overall (westward) topographic slope. They also appear to be rotated westward from the generally north-trending regional orientation of faults in this section of the Wasatch Front, seen in Figure 10.

Many of the creeks in the vicinity of the study area have a linear appearance. The easiest places for streams to erode should be where the bedrock is already weakened by tectonic deformation. Thus it is believed that the paths of streams reflect the trends of faults or fracture zones in the bedrock. The general trend of stream channels is approximately  $270^{\circ}$ .

Large pegmatite bodies in the study area crop out across the slope, and trend along a range of azimuths from  $302^{\circ}$  to  $333^{\circ}$ . Locally, they dip gently eastward, as shown in the geological map of the study area (Figure 11).

### Discussion

Statistical and geological analyses of fractures show that the dominant characteristic of fracture patterns is

their great spatial variability. However, lithology is a spatially consistent control on the style and orientation of fracture populations. The distribution of fractures in gneissic rocks is significantly non-random. The principal orientation of fractures in pegmatites is different from those in gneiss and amphibolite.

It is concluded that an overall fracture pattern does exist, which was mainly imprinted by stresses associated with the Sevier and Laramide orogenies. The geological complexity of the Farmington Canyon Complex is responsible for widely disparate fracturing styles at different localities.

Rotation of the fracture sets suggests that:

- 1) major lineaments in the study area that trend along azimuth  $290^{\circ}$  are subparallel to the direction of the greatest principal stress during the Sevier orogeny, and that

- 2) the majority of rotated fractures are orthogonal to this direction (i.e., parallel to the least principal stress during Sevier compression), and therefore may be "relaxation" fractures, which have been further opened by Basin and Range extension. This subsequent extension may also explain why the northeast-trending fractures are better represented at the outcrop than other orientations of fractures in the study area.

Regions classified according to their geomorphology appear to have significantly different fracturing styles. It is most likely, however, that their geomorphology is a function of their geology. It is concluded that regional tectonic stress, followed by folding, and compounded by lithological variation, along with an unknown degree of topographically induced sampling bias, has resulted in the observed distribution of fracture and foliation orientations in the study area.

## HYDROGEOLOGIC IMPLICATIONS OF BEDROCK STRUCTURE

This section integrates information from multiple sources in an attempt to comprehensively describe the hydrogeology of the Farmington Canyon Complex in the study area. Before addressing the the hydrological implications of the bedrock structure, some general properties of this and other consolidated bedrock aquifers are discussed.

### Regional Hydrogeology in the Basin and Range

Circulation of ground water through deep flow systems contributes significantly to the hydrologic balance in the southwestern Basin and Range province. Mifflin (1968) emphasizes the importance of interbasin flow for the Nevada water budget. He states that avenues for water transport through carbonates exist at great depths along shear zones created by intense and repeated structural deformation associated with the development of the Basin and Range. Continuous interbasin flow has maintained or enlarged these flow routes. The author mentions that deep flow systems may also be present in lithologies other than carbonates (Mifflin, 1968).

In the Death Valley salt pan of California, major differences in water chemistry were found between springs on the eastern and western edges of the salt pan (Hunt and Robinson, 1960). The authors attribute this to interbasin flow along faults connecting the eastern springs to

Mesquite Flat, 16 km northwest in an adjacent basin. Springs on the western edge are linked to Ash Meadows Springs, 80 km to the east (Figure 51). The differences in water chemistry shown in Figure 52 support the authors' hypothesis.

Recharge from mountain blocks bordering alluvial valleys in the Basin and Range province accounts for a substantial portion of the available ground water. Extensively fractured bedrock, underlying saprolites and colluvium, can constitute a large ground-water reservoir (Mundorff et al., 1963). Discharge is via springs, or directly into the valley alluvium at depth (Figure 53).

#### **Hydrogeology of the Farmington Canyon Complex**

Little has been written about the hydrogeology of this part of the Wasatch Front. A study by Feth (1964) shows evidence of recharge to the Jordan Valley (Lake Bonneville sediments) from the Farmington Canyon Complex. He cites water chemistry similarities, analogous seasonal level fluctuations in mountain and valley water tables, and the position of equipotential lines in concluding that the mountain block is an aquifer which provides significant recharge to the basin reservoir. Feth (1964) also mentions that during the construction of Gateway Tunnel, a water supply tunnel dug parallel to the Weber River, a ground-water source was encountered approximately 305 m into rocks of the Farmington Canyon Complex, which yielded a steady discharge of 19 to 38 l/s.

Figure 51. Location map of the four springs discussed in the text (after Hunt and Robinson, 1960).

**Figure 52.** Histograms comparing the water chemistry of springs at Mesquite Flat (1), western Death Valley (2), eastern Death Valley (3) and Ash Meadows (4). 1=Ca; 2=Mg; 3=Na; 4=K; 5=HCO<sub>3</sub>; 6=SO<sub>4</sub>; 7=Cl; 8=As(x100); 9=Sr; 10=F; 11=B (adapted from Hunt and Robinson, 1960).

Figure 53. Schematic diagram suggesting paths by which recharge through jointed crystalline rocks reaches aquifers in alluvial basins (after Feth, 1964).

Feth's study is primarily concerned with the state of the alluvial aquifer at the base of the Wasatch Front. He does not discuss ground-water discharge within the mountain block, which is the concern of this study. The cross-sections in Figure 54 were developed from investigations in the study area. They show inferred downslope ground-water flow paths, and different bedrock controls on ground-water discharge. The locations of these cross-sections are shown in Figure 11.

Many springs and seeps are known to exist along the Front (Skelton, 1990; Olson, 1985). A number of springs in Rudd Canyon were developed to supply water for the town of Farmington. These springs were abandoned when they could no longer meet demand and a water supply aqueduct became available (Keaton, 1987).

A number of springs were observed in the study area during the summer of 1988. Outflow from one of these (shown with a star in Figure 11) was measured on a daily basis after a significant local rain on August 8, 1988. A best-fit recession curve was plotted for these data (Figure 55). Recession curves can be used to estimate aquifer properties, including specific yield (Weeks, 1964; Domenico, 1972). Fractured aquifers in crystalline rock generally have low porosity, and therefore low specific yield (Freeze and Cherry, 1979).

The base discharge for the spring is unknown; but the

**Figure 54.** Geologic cross-sections AA' and BB' from Figure 11. Arrows show inferred paths of ground-water flow. Discharge is due locally to the influence of faults or lithologic contacts.

Figure 55. Decline in spring flow after a rainstorm on August 8, 1988. Time (x-axis) is measured in seconds, starting from 0 at the time of the first measurement.

presence of a large pond fed by this and other local springs implies that it does not dry up completely during the year. Projected forward, the spring discharge curve decreases to 0.1 l/s in just over 46 days. The total volume of water discharged by the spring over this time is approximately 765,695 l, or 766 m<sup>3</sup>.

This result indicates that the specific yield of the aquifer tapped by this spring is low. This means that for a given recharge volume, the aquifer fills up more rapidly than a porous medium aquifer with a greater specific yield. Thus a critical pore water pressure can be achieved earlier in these fractured rocks than in porous media, assuming the head difference is the same for the two cases.

It could be argued in this case that the rapid decline in spring flow is simply due to the aquifer having a very limited areal extent. A small, highly permeable porous media aquifer would behave in the same way. Indeed, it is likely that structural and lithological heterogeneities compartmentalize the bedrock aquifer to a considerable extent. However, some new springs emerging from debris flow scars in this area have flowed continuously for up to five months after the event. Springs feeding a stream in Lightning Canyon, north of the study area, had a total estimated discharge of 388,000 m<sup>3</sup> for the calendar year 1984 (Mathewson et al., 1990). In

view of the inferred low specific yield of the rocks that make up the aquifer, this implies that the areal extent of aquifer compartments can be very great, and that large sections of the subsurface are in hydraulic communication.

Sustained post-storm flow can be seen in the hydrograph of Halfway Creek, a tributary of Farmington Creek, just north of the study area, shown in Figure 56 (Davis County Planning Commission, 1989). A storm on August 10, 1989 caused an immediate rise in the stream level, due to surface runoff. The stream level then decreased to 10 cm above pre-storm levels, and stayed constant for at least 26 hours.

Halfway Creek is in a steep tributary canyon of Farmington Creek. Aerial photographs show that bedrock exposures are common, especially on the southeast-facing flanks. It appears that colluvial cover is minimal on these slopes, particularly on the southeast-facing flanks. In addition, some large contour trenches have been cut into the head of the drainage; these probably enhance recharge to the fractured bedrock. In view of the character of the Halfway Creek watershed, it is concluded that the hydrograph in Figure 56 shows post-runoff drainage out of a fractured bedrock aquifer.

#### **Directional Permeability of Fractured Rocks**

The Farmington Canyon Complex consists primarily of crystalline rocks, which generally have very little

**Figure 56.** Hydrograph of Halfway Creek, showing the response of stream level to a rainstorm on August 10, 1989.

intergranular porosity. However, the rocks are ubiquitously fractured. In this study, it is assumed that fractures control the porosity and permeability of the bedrock. As a result, the permeability may be highly anisotropic, making it very difficult to predict flow paths (Neretnieks, 1985).

Much work has been done on evaluating reliable permeability parameters in fractured rock. The recent interest in tracing the flow directions of solutes in ground water has added momentum to this research. Studies generally approach the subject from opposite extremes: the microscale (non-continuum) or the megascale (continuum). The megascale approach is to evaluate basin-scale regions in terms of average values of hydraulic conductivity and effective porosity. Results can be very useful but may mask important local anomalies.

Examples of microscale work are papers by Witherspoon and others (1980) and Brown (1987), who discuss the applicability of the parallel plate model for flow through a single fracture, first put forward by D. T. Snow in 1965. The basic equation is derived from Darcy's Law: flow rate is proportional to the difference in hydraulic head and the fracture aperture cubed (Gale et al., 1985, p. 1). The model appears to be reliable in laboratory experiments, for a range of fracture apertures (down to 4 microns), even when surfaces are quite rough (Witherspoon

et al., 1980; Brown, 1987).

It is difficult to adapt such detailed theoretical studies to realistic in situ conditions, especially when dealing with an extensive and geologically heterogeneous study area. Complex numerical methods have been developed for this (e.g., Long and Witherspoon, 1985). Another method of characterizing the hydraulic conductivity of an area is to interpolate between known values (such as boreholes) using geostatistical methods (Jones et al., 1985). If fracture density is great enough, the aquifer can be modeled as an equivalent anisotropic porous medium (Greenkorn et al., 1960; Long et al., 1985).

#### **Fracture Connectivity**

Long and Witherspoon (1985) found that the degree of interconnection of a network of fractures greatly affects its hydraulic conductivity. LaPointe and Hudson (1985) used a printed electrical circuit board analog to model two-dimensional hydraulic conductivity. They found that the direction of greatest hydraulic conductivity was approximately parallel to the direction of maximum fracture interconnectivity.

Taylor and Fleming (1988) used azimuthal resistivity surveys (Wenner array) to characterize the hydraulic conductivity of fractured rocks. In all cases, they found that the major axis of the resistivity ellipse corresponded to the direction of greatest hydraulic

conductivity. This direction also coincided with the direction of greatest joint connectivity (Taylor and Fleming, 1988). Based on this work, it is believed that the principal direction of fracture intersection lines (shown for regions 1 through 8 in Figure 49) is a good indicator of the direction of maximum bedrock permeability, at least in areas unaffected by large-scale features such as faults or major lithological boundaries.

### Effect of Large-Scale Features

#### Regional Ground-Water Flow

The principal trend of faults interpreted from aerial photographs in the study area is  $290^{\circ}$ . The trend of pegmatite outcrops across the study area is between  $302^{\circ}$  and  $333^{\circ}$ . In contrast, the principal strike of fracture sets is  $223^{\circ}$ , and, based on Figure 49, the principal trends of fracture intersection lines are  $22^{\circ}$ ,  $54^{\circ}$  and  $215^{\circ}$ , with very flat plunges. It has not been possible to directly assess the relative contribution of each type of structural discontinuity to regional permeability trends in this part of the Farmington Canyon Complex. Some indirect comparisons have been made using available data, to infer the dominant trend of ground-water transport, and hence to identify the most influential bedrock feature(s).

Figure 57 shows the location of several creeks flowing through rocks of the Farmington Canyon Complex along the Wasatch Front. Discharge data from these creeks

**Figure 57.** Location of creeks along the Wasatch Front that were used in the comparison of normalized discharge.

for the available years are shown in Figure 58. Discharge data were obtained from United States Geological Survey records, for the years 1952 through 1963. Average annual discharge has been divided by the drainage basin area to normalize the values. Overall, the pattern is of increasing discharge northward. An explanation for this trend is that northwestward "inter-canyon" transfer of ground water takes place at depth along faults and fracture zones.

The exception to this trend is Centerville Creek, which has a higher discharge per drainage area than Parrish Creek even though it is located southward of it. Possible reasons for this are: 1) Centerville Canyon has a different land use history than the other creeks. It is the only one whose pristine condition has been preserved (Croft and McDonald, 1944). Thus, clayey residual soils may be better developed, inhibiting recharge to deep bedrock conduits, and directing interflow back into Centerville Creek. 2) A broad area to the southeast of Centerville Canyon is free of other canyons. Thus Centerville Creek may be recharged by ground water moving along northwest-trending fault zones. The southeast flank of Parrish Canyon is much narrower, so recharge to deep structures is likely to be much less.

**Figure 58.** Discharge data for the years 1951 through 1963 show that, except for Centerville Creek, discharge per unit area of drainage increases northward.

### Debris Flow Initiation and Prolonged Discharge

The largest debris flow along the Wasatch Front during 1983 was in Rudd Creek. Approximately  $63,000 \text{ m}^3$  of material was deposited at the mouth of the creek (Keaton, 1988b). After the debris flow at Rudd, water continued to flow out of the slide scar well into the summer (a small but steady stream was observed there by this writer in August 1988).

Figure 59 shows the topography of the area around the Rudd Creek debris flow scar. Failure occurred at an elevation of approximately 2109 m. Thus the maximum head that could have developed, from the highest point in the recharge area to the failure scar, is approximately 420 m, equivalent to  $42 \text{ kg/cm}^2$  in an open conduit. Even through a network of fractured rock, substantial pressures would be generated. However, it seems unlikely that the small recharge area directly above Rudd Creek (shown with a dotted line in Figure 59) could have sufficient storage to provide water for year-round flow.

Taking into account the possibility of cross-slope discharge along a fault, the recharge area for Rudd Creek can be greatly expanded (Keaton, 1988a). The inferred boundary for the structurally-controlled recharge area is shown with a dashed line in Figure 59. In addition, approximately 116 m can be added to the pressure head column above the point of debris flow initiation.

Figure 59. Boundary of the topographically-controlled recharge area for the head of Rudd Creek is shown with a dotted line. Inferred boundary of the recharge area controlled by bedrock structure is shown with a dashed line. Faults are heavy solid lines. Note debris flow failure scar and spring in northwest corner.

## Structural Fabric and the Distribution of Slope Failures

### Slope Aspect

In order to assess the relative contribution of fractures and faults to the initiation of slope failures, the aspects of slopes (i.e. the direction faced by the slope) on which slope failures occurred were measured for 74 mapped shallow landslides and debris flows (compiled by Lowe, 1989). Slope aspect at the failure scar was determined at the highest point of the failure. A sampling circle with a diameter equal to twice the width of the widest mapped debris flow scar was used to standardize the areas measured. The circle was positioned such that the topographic contour nearest to the failure scar touched the circle on diametrically opposite sides. The direction of the (downslope) normal to this diameter was taken to be the aspect of the slope failure.

It was thought that slopes perpendicular to structural features conducting significant amounts of ground water would have the greatest chance of experiencing high pore water pressures leading to slope failure. Conversely, slopes parallel to discontinuities would have little chance of intersecting major ground-water pathways, and should therefore have fewer slope failures. This analysis assumes that all other conditions are the same for the slopes.

Figure 60 shows that the majority of slope failures occurred on slopes facing azimuth  $290^{\circ}$ . This corresponds to the orientation of large scale structural lineaments in the study area. There are very few slope failures on slopes facing azimuth  $110^{\circ}$ , diametrically opposite  $290^{\circ}$ . This is because of the general westward aspect of this section of the Wasatch Front.

There is no increase over background in slope failure occurrences for any other azimuth. Therefore, it does not appear that the main trends of fractures, fracture intersection lines, or pegmatites in the study area play a significant role in the regional control of ground-water flow paths. However, these may be more important in contributing to local failure mechanisms, as discussed below.

#### **Daylighting Fracture and Foliation Planes**

There is some evidence that gently-dipping bedrock discontinuities exert a more localized control on the initiation of debris flows. One of the possible failure mechanisms discussed earlier involved gently-dipping fracture and foliation plane sets intersecting the slope at the base of the soil mantle, and thus allowing communication between the bedrock aquifer and the surface (Figure 4). For these gently-dipping planes, dip direction rather than strike was considered to be more important in controlling ground-water flow paths.

Figure 60. Slope aspect, shown as the normal to the trend of the slope, for 74 mapped slope failures.

Figure 61 shows the location, dip angle, and dip direction of principal foliation planes and fractures that dip less steeply and up to  $10^\circ$  steeper than the topographic slope. (The latter were included because slope angles might locally be steeper than the mean angle calculated from the topographic map). Figure 62 is a rose diagram of the dip directions mapped in Figure 61. Three major trends are apparent; toward azimuths  $45^\circ$ ,  $235^\circ$  and  $296^\circ$ .

The location of data points depended on the distribution of accessible outcrops, so the direct utility of this analysis is limited with respect to areas susceptible to soil slips or debris flows. Most of the gently-dipping discontinuities were found on ridges, where there is little or no soil cover, and no hydrostatic column within the aquifer. The swales, where such data would have been most useful, were often covered by vegetation, or were too remote. However, the fracture and foliation sets shown in Figure 61 may persist within the local area, so it may be possible to extrapolate the effect of daylighting planes to swales adjacent to the outcrops shown. Information from Figure 61 forms part of the composite map of structural features and mapped slope failures compiled by Lowe (1989), shown in Figure 63 (in pocket).

Figure 61. Location, dip directions and dip angles of principal fracture sets that dip less steeply, and up to  $10^\circ$  more steeply, than the topography.

**Figure 62.** Rose diagram of the dip directions of low-angle discontinuities mapped in Figure 61.

Another thing to note about Figure 62 is that many of the locations are included because of having extremely steep slopes rather than extremely flat discontinuities. Such steep slopes are unlikely to be the sites of landslides or slope failures, because of a lack of soil development. However, the locations do correlate with several rock failures observed in the study area, particularly on the east side of the ridge crest.

Gently-dipping contacts between gneiss and pegmatite were also proposed as potential sites for ground-water discharge and/or slope failure (Figure 5). In Ford Canyon, a shelf-like pegmatite outcrop trends across the slope, and is associated with several springs and at least one recent shallow soil slip (Figure 64). Pegmatite outcrops have also been included in Figure 63 (in pocket).

### Discussion

What appears to exist in the region are two separate structural and ground-water environments, conceptually divided into "shallow" and "deep". Each exerts different controls on ground-water flow. Where they are in communication, the potential for prolonged discharge or a rise in pore water pressure is increased. Thus, the controlling influence on ground-water discharge of a given spring or seep is how well it is connected to a high volume compartment within the aquifer.

Figure 64. Oblique aerial photograph (looking east) of pegmatite outcrops cutting across slopes in the study area. Arrow shows Ford Canyon swale (site of a WADI survey) underlain by a pegmatite unit. Directly west of the flat swale is a wide, shallow soil slip.

At a regional scale, major structural lineaments may be responsible for significant cross-slope transport of ground water. More locally, heterogeneities in lithology and bedrock discontinuities control the distribution of discharge points. The cross-slope trend of low-permeability rock units, together with the dip directions of low-angle discontinuities (Figure 62) identify the particular slopes on which ground-water discharge is more likely to take place.

## GEOPHYSICAL SURVEYS

### Introduction

Three geophysical surveys were conducted in the study area to get an idea of bedrock structural fabric at depth. The VLF (very low frequency) electromagnetic method was used, with a hand-held receiver marketed under the name of "WADI" by Saga Geophysics of Austin, Texas. The instrument makes use of an existing 15-30 KHz EM field emitted by various stations around the world, normally used for worldwide navigation purposes.

### Theory

The horizontal component of the magnetic field reaches the study area. When a steeply dipping planar subsurface conductor (for example, a fracture containing ion-rich water) is encountered by the primary field, eddy currents are induced on the edges of the conductor; an associated vertical magnetic field is induced. The WADI measures the addition of the primary (source) and secondary (induced) fields, thus yielding a ratio of  $([e_p + e_s]/e_p)$  denoted as "ECD" (equivalent current density), where  $e_p$  is the in-phase component of the primary magnetic field and  $e_s$  is the in-phase component of the secondary magnetic field. In this way, conductive planar features in the subsurface are recorded as positive anomalies over a background established for the survey.

The magnitude of the quadrature, (i.e. the vertical, out-of-phase component) of the secondary magnetic field gives a measure of the capacitance, or ability to hold current, of the subsurface conductor. The larger the quadrature, the greater the capacitance of the feature; thus fractures filled with saturated clays or metallic mineralization, being excellent conductors, should have high values for both ECD and quadrature. Fresh-water-bearing fractures are much less conductive, though still more conductive than most rock, especially dense metamorphic rock; thus they do not hold current well, and should have lower quadrature values (Morgan, 1990; Saga Geophysics, 1989).

Intact crystalline rocks typically have very high resistivities, as shown in Table 6. Therefore, saturated fractures or fracture zones are likely to be represented by lower resistivity (higher conductivity) values over a background established in rocks of the Farmington Canyon Complex. These would be recorded as positive conductivity anomalies by the WADI.

For this study, anomalously high ECD values occurring in conjunction with low quadrature values were taken to be water-bearing fractures. The following hypothesis was advanced: linear conductivity anomalies are water-bearing fractures that represent preferential pathways for groundwater flow through bedrock. Conversely, if the bedrock is

so pervasively fractured that it is isotropically and homogeneously permeable to ground water, conductivity values will be relatively uniform.

Table 6. Resistivities of some consolidated and unconsolidated rocks. Note that unconsolidated sediments have much lower resistivities than consolidated rocks (adapted from a table compiled by Heiland, 1968).

<u>Material</u>	<u>Locality</u>	<u>Res. (Ohm-m)</u>
<u>Lab specimens:</u>

Silt (dry)	Montana	20

### Survey Techniques and Results

A VLF transmission station in Seattle, Washington was used for all the surveys. This station transmits a 125 kW, 24.8 kHz signal; thus its wavelength is approximately 20 km (Halliday and Resnick, 1978). As discussed below, it is preferable to use at least two transmitters for any VLF survey, but this was not done in the study area.

### Steed Canyon Survey

A VLF survey was carried out in Steed Canyon, in two adjoining swales along the northern flank of the canyon (Figure 65). The eastern swale is the site of a 1983 landslide and debris flow that has been studied by researchers at Utah State University (Brooks, 1986; Monteith, 1988). The bedrock in this area consists of layered to migmatized gneiss, some of which grades into amphibolite. No pegmatites were found in the surveyed area. The two swales contain a relatively thicker soil column than the surrounding slopes.

Four parallel conductivity profiles were recorded at this site. Each reading was spaced 10 m apart, and profiles were 30 m apart. The results were contoured in separate maps for ECD and quadrature, shown in Figures 66 and 67.

Figure 68 shows the general topography of the survey area. In the east swale, ECD values are generally low. There is an elongate zone of higher ECD on the eastern flank of the ridge separating the two swales; this also corresponds to a quadrature high. This feature is interpreted to be a north-trending fault or fracture zone containing moist clayey material. In the west swale, there is a relatively higher ECD zone trending northwest across the swale axis. There is no increase in the quadrature over the area, so this feature could be a

Figure 65. Location of the WADI surveys in Steed and Ford canyons.

Figure 66. Contoured ECD values from the Steed Canyon WADI survey. Conductivity anomalies trend north in the east swale, and northwest in the west swale.

Figure 67. Contoured quadrature values from the Steed Canyon WADI survey.

Figure 68. Generalized topography of the Steed Canyon WADI survey area and location of the Steed Canyon landslide and debris flow. Also shown are the locations of boreholes from a study by Brooks (1986). In the text, boreholes in the east and west swales are distinguished by E or W before the borehole number.

broad, unevenly saturated fracture zone with little or no clay.

West of and sub-parallel to this zone is a narrow trend of negative ECD and quadrature values. This feature, located on the western edge of the west swale, could be interpreted either as a hard bedrock ridge or as an unsaturated fracture zone. Finally, an ECD high on the far west side of the survey corresponds to a quadrature high, and appears to be another clay-filled structure.

In a previous study, Brooks (1986) logged several boreholes in each of the Steed Canyon swales. Figure 68 shows the locations of the boreholes. In the east swale, almost all the borings encountered a layer of rock or rock fragments at approximately 3 m. Soils beneath this layer were found to be non-plastic. In borings E1 and E1B, a plastic, silty to clayey sand layer was found overlying the ledge. If it is assumed that higher plasticity corresponds to lower hydraulic conductivity (Brooks, 1986), then it is possible that ground water in and under the fractured ledge was prevented from discharging, and pore water pressures built up to a critical level in the vicinity of E1 and E1B.

Borings in the west swale indicated the presence of a rocky ledge which divides the swale into an upper and a lower part. Brooks (1986) found evidence of large voids in the bedrock in borehole W5. A water hose with 122 m of

head on it failed to fill borehole W6B, "regardless of the quantity of water poured down the hole" (Brooks, 1986, p. 46). Boreholes 5 and 6B in the west swale correspond to the edges of the northwest-trending low-conductivity anomaly found by the WADI. This supports the interpretation of the anomaly as an unsaturated fracture zone. It appears, therefore, that a deep, highly permeable fracture zone cuts across the west side of this swale, which is capable of draining great volumes of water during flood conditions, but is dry for most of the year. This feature probably prevented the development of elevated pore water pressures in the west swale during May and June of 1983 and 1984, which may explain why slope failure did not occur in this swale.

In the Steed Canyon survey, the overall low ECD values in the hollows compared with the ridges are thought to be due to masking of the signal by electrically conductive clays in the subsurface. Topographic ridges have higher ECD values, consistent with the greatly decreased (to non-existent) soil cover in these areas. In addition, the depths of conductors found by the WADI are greater on the ridges: between the two swales, these values range from 2 to 10 m, averaging 6.3 m; on the ridge west of the western swale, values range from 4 to 16 m, averaging 9 m. In the hollows, the depths of conductors average 3.2 m (east swale) and 5.4 m (west swale). Brooks

(1986) found the depth to "true" bedrock (not the rocky ledge) to be between 5 and 10 m for the east swale, and between 3.7 and 12 m for the west swale. This range is similar to the depths of the conductors recorded on ridges by the WADI, which appears to be more realistic than the depths recorded in the hollows.

Monteith (1988) mentions that the clay layer in the east swale is thick at the downslope end of the swale, and thins upslope. This correlates with higher ECD values at the north edge of the WADI survey, and supports the claim that readings were suppressed by electrically conductive clayey soils toward the south.

The WADI also indicates the apparent dip of a planar conductive feature, by determining the lateral changes in conductivity at different depths for a given conductivity peak (Karous and Hjelt, 1983). Table 7 shows the distribution of dips for the Steed Canyon survey area. Since the survey was carried out along azimuth  $270^{\circ}$ , all values are apparent dips along this strike. The majority of features have a westward apparent dip, at an average angle of  $42^{\circ}$ . Table 7 shows that this is not in agreement with the fracture and foliation orientations measured at the surface.

The validity of dip values given by the WADI is questionable for this survey. Furthermore, it is unlikely that individual fractures are being recorded by the WADI.

Table 7. A. Apparent dip angles and directions for planar conductivity anomalies in the Steed Canyon survey area. B. Dip angles and directions for principal orientations of (i) fractures in the area adjacent to the northern mapped fault (data set XNFC), and (ii) foliations over the entire study area; both projected along the same strike (az.  $270^{\circ}$ ) as the WADI survey line.

<u>Dip direction</u>	<u>Avg.Dip angle</u>	<u>Std.Dev.</u>	<u>Number</u>
A) <u>WADI:</u> west	$42^{\circ}$	$11^{\circ}$	14
east	$28^{\circ}$	$5.5^{\circ}$	5
vertical	$90^{\circ}$		1
B) <u>OUTCROP:</u>			
(i) Fractures from data set XNFC:			
east	$84^{\circ}$		
(ii) Foliations over entire study area:			
west	$23^{\circ}$		
(iii) Geomorphic region 7: no resolvable principal sets.			

It is more likely that a larger feature such as a fault or fracture zone is being recorded. In Figure 69 a line of anomalies appears to trend northwestward (approximate azimuth  $315^{\circ}$ ) across the survey area. This follows the trend of the broad, high ECD/low quadrature zone shown in Figures 66 and 67, and may be more representative of the scale of bedrock features best suited for investigation by the WADI.

#### Ford Canyon Surveys

Two surveys were run in the upper part of Ford Canyon. The survey areas are located on the flank and at the base of a large swale which appears to have been the site of Holocene land slips (Lowe, 1989). The location and topography of the survey areas are shown in Figure 70.

Figure 69. Location, apparent dip angle and dip direction of planar conductors interpreted by the WADI. Note the northwest trend of conductors across the west swale.

**Figure 70.** Location and topography of the upper and lower Ford Canyon swale WADI surveys. Note the pond created by a beaver dam.

This swale is underlain by a gently eastward-dipping series of interbedded pegmatite and gneiss units of varying thickness. At least one shallow soil slip from 1984 is located at the head of the steeper slope just beyond the western edge of the swale. No direct subsurface information was available for these sites, although the descriptions in Harp and others (1990) indicate that the soil stratigraphy is similar to that of the Steed Canyon area.

Contour maps were generated for ECD and quadrature for the upper and lower Ford Canyon surveys, as shown in Figures 71 through 74. Linear conductivity anomalies for both surveys trend approximately due north and due west. The quadrature for the entire lower swale is near zero, except in the northeastern and southern corners (Figure 74). In the upper swale, ECD highs roughly correspond to quadrature lows. Therefore it is reasonable to conclude that these linear anomalies are water-bearing fracture zones. The west-trending subsurface features parallel the general orientation of fractures measured at the outcrop for pegmatites, shown in the lower hemisphere plot in Figure 41 C.

The low ECD values along the southern edge and in the northeastern corner of the lower Ford Canyon swale survey (Figure 73) indicate the presence of extremely poor conductors. These are discussed below.

Figure 71. Contoured ECD values for the upper Ford Canyon swale WADI survey. Linear anomalies in the center of the plot trend approximately north and west.

Figure 72. Contoured quadrature values for the upper Ford Canyon swale WADI survey.

Figure 73. Contoured ECD values for the lower Ford Canyon swale WADI survey. Anomalies trend north and west.

Figure 74. Contoured quadrature values for the lower Ford Canyon swale WADI survey.

Dips recorded by the WADI in the upper and lower Ford Canyon Swale surveys are compared with outcrop-derived orientation data in Table 8 below. Apparent dips do not appear to match between surface information and interpretations made by the WADI.

**Table 8. A.** Apparent dips of conductors in upper and lower Ford canyon swales, from WADI. **B.** Dip directions and apparent dip angles for (i) fractures adjacent to the central fault (data set XNFD), and (ii) fractures in pegmatite over the entire study area.

<u>Dip Direction</u>	<u>Avg.Dip Angle</u>	<u>Std. Dev.</u>	<u>Number</u>
<b>A) <u>WADI:</u></b>

east	76°		
(iii) Geomorphic region 2: no resolvable fracture sets.			

The depths to conductors in the Ford Canyon surveys are shown in Figures 75 and 76. There was no independent subsurface information with which to compare these readings. The north-trending, higher ECD zone in Figure

**Figure 75.** Apparent dip angle and dip direction of planar conductors interpreted by the WADI, for the upper Ford Canyon swale.

**Figure 76.** Apparent dip angle and dip direction of planar conductors interpreted by the WADI, for the lower Ford Canyon swale.

73 (lower swale) corresponds to depth readings in Figure 76 which average 13.4 m. This may indicate the depth to water in the fractured bedrock. In contrast, the west-trending higher ECD zone at the slope break averages 7.9 m in depth. Both of these readings appear too deep, considering the numerous springs and seeps in the immediate area. No individual trends are distinguishable in the upper survey.

The depths to conductors recorded by the WADI in these surveys are highly variable. This is consistent with the picture of the subsurface obtained from boreholes in the Steed Canyon survey area. In general, little can be concluded from the data on the dip of, or the depth to, conductors in the two Ford Canyon surveys, beyond the fact that the soil/bedrock interface is highly irregular.

A curious feature in the lower Ford Canyon swale survey is the pattern of strong negative values at the southern edge and northeastern corner of the survey. Assuming these are not due to instrument malfunction, they may be due to distortion of the primary magnetic field by topographic effects, because the anomalous values correspond approximately to the edge of steeper slopes on the southeastern edge of the swale. Another possible cause for the low conductivity readings is that the water table is deeper in these zones of higher topography, although evidence from the Steed Canyon survey showed a

general increase in conductivity over topographic highs. A third possibility is that the negative anomalies are electrical edge effects on either end of a conductive zone of saturated fractured bedrock (seen as a long west-trending higher ECD zone in the southern part of the survey in Figure 73).

A hypothesis for the development of the apparent bedrock ground-water condition in the lower Ford Canyon swale is that the bedrock ledge north of the slope break has been downdropped, forming a shelf which has become a ground-water discharge area, as well as a repository for residual soil and colluvium. Ground water has been impounded due to the (post-faulting) geometry of the less permeable bedrock. A conceptual diagram of this feature is presented in Figure 77.

The presence of springs and seeps as well as water in fractures (inferred from the Wadi survey) during August 1988, one of the driest summers on record for this region, indicates perched water table conditions. Discharge through this system is probably greatly increased during times of peak runoff and snowmelt. This area of ground-water discharge was created by the anomalous presence of a relatively less permeable rock body, as shown schematically in Figure 5. The area is presented as one example of bedrock control over ground-water discharge and/or slope failure in the study area.

**Figure 77.** Schematic diagram of the site of the lower Ford Canyon WADI survey. The pegmatite unit underlying this area has been down-dropped across a fault or fracture zone trending approximately due west. This has created a ground-water discharge zone throughout the Ford Canyon Swale. The fault hanging wall is marked with hachures; a and b denote the low ECD areas next to the fault scarp; the patterned area shows high ECD, corresponding to saturated fractured bedrock.

## Discussion

### Method

The WADI, and the VLF method, are excellent reconnaissance tools for a number of reasons. The WADI is light and compact; it was found to have great utility in the rough terrain of the study area. Surveys for quite large areas can be conducted rapidly. Each data point recorded in a survey contains information on in-phase and out-of-phase components of the induced field. Anomalies can be interpreted in situ. The lateral and vertical position of the anomaly, and a value for the dip of the feature are presented graphically. Up to approximately 4000 measurements can be held in the memory (Saga Geophysics, 1988).

The low frequency of the waves allows them to penetrate some distance into the ground, depending on the conductivity of the material. The remoteness of the primary field source means that the field is essentially uniform for surveys of the size used in this study (Telford et al., 1985).

### Interpretation of Results

The principal drawbacks of this method, as with any geophysical method, lie in the ambiguity of the results. Some of the causes of ambiguity are listed below.

- 1) Resolution is poor; conductive features must be on the order of 10 m or more in length to be detected.

2) The dip of the subsurface conductor affects the magnitude of the secondary field. Since the primary field is dominantly horizontal, more steeply dipping planes present a larger conductive area; so the greater the dip, the greater the induced field. Thus an apparently poor conductor may simply be oriented near to horizontal, while a less conductive, more steeply dipping feature may appear to be a stronger conductor than it really is.

3) In order for the secondary field to be maximized, the subsurface conductor must be aligned perpendicular to the primary field. Deviation from this orientation results in distortion of the secondary field read by the VLF instrument. If the primary field is near parallel to the trend of the conductor, the secondary field may be severely inhibited (Telford et al., 1985). Thus it is recommended that the same area be traversed at least twice, using different stations for each survey. This was done by White and Gainer (1985), in their reconnaissance for fractures around a uranium mill tailings pond.

4) The WADI measures all conductivity values with respect to the first data point of the survey. Thus, if the first point is taken on a highly conductive (or highly resistive) material, subsequent points might all show excessively low (or high) conductivities because of the contrast with the first point. However, relative values should not be affected. In this study, a procedure

suggested by Morgan (1990) was followed, in order to normalize conductivity values between surveys. The average conductivity over the entire survey was calculated, and was set equal to zero. The data for that survey are then shifted by the same amount. All the ECD and quadrature grids shown in Figures 66, 67, and 71 through 74 were normalized to their average value.

5) Results can be affected by topography, and by the in situ properties of surface and subsurface materials. Topography can affect induced conductivity readings by "channelizing" the primary field and creating higher readings in valleys than on ridges (Morgan, 1990). It is not known how local topography has affected these results, though Lagmanson (1990) states that the filtering method incorporated into the WADI accounts for topographic changes. At any rate, the Steed and lower Ford Canyon swale surveys have opposite correlations with topography (Figures 66 and 73), so other factors must be more important than topography in producing the observed conductivity distributions.

6) Changes in the conductivity of the overburden may mask the response from bedrock; highly conductive surficial materials such as clays may completely preclude this method (Saga Geophysics, 1988). However, surface water bodies do not induce a noticeable secondary field, probably because of their horizontal upper surface; this

was observed in the lower Ford Canyon swale, where a beaver dam has impounded spring discharge (Figure 70).

In contrast to surface water, subsurface clayey zones may have a near-vertical tabular geometry, as in the case where a highly fractured or weathered zone has been filled by clay minerals. Clay-filled fractures should be distinguishable from water-bearing fractures by the magnitude of their quadrature.

Finally, as with any geophysical method, it is important to have independent geological verification of the results. This type of supporting data was lacking in the Ford Canyon study area.

#### Summary

The clayey subsoils which are present in the Steed Canyon survey area (Brooks, 1986) and probably also in the Lower Ford Canyon swale, may have dampened the secondary field response from deeper conductive features in the bedrock. In spite of this, several linear anomalies were recorded.

A trend of anomalies was recorded by the WADI in the Steed Canyon survey, along azimuth  $315^{\circ}$ . This does not correspond to the trend of the fault mapped through this region using aerial photographs and surface information (azimuth  $290^{\circ}$ ). However, north-trending anomalies in the east Steed Canyon swale, and north and west-trending anomalies in the Ford Canyon swales do correspond to the

trends of faults and fracture sets observed at the surface.

The WADI survey in Steed Canyon correlates with a change in soil properties found in borings (Brooks, 1986), and may have identified a fault or fracture zone in the west swale. In Ford Canyon, little direct confirmation of the WADI data was available. Conductivity anomalies were generally aligned due north and west, and a possible fault-controlled ground-water discharge mechanism was hypothesized for the lower swale. The geophysical data correlated well with surface observations, and were supported by geomorphic and hydrologic evidence.

## SUMMARY AND CONCLUSIONS

This study has attempted to characterize the large and small scale structural fabric of the Farmington Canyon Complex, to infer ground-water flow directions in the bedrock, and to determine the distribution of ground-water discharge points at the surface. Several slope failures in the study area were initiated by ground-water discharge; thus the main application of this research was to establish a link between the structural fabric of the bedrock and the distribution of slope failures.

The following sections summarize the findings of this research. The bedrock features and distribution of slope failures discussed in this section refer to several different figures in the text. Most of these are combined in Figure 63 (in pocket).

### Structural Fabric

#### 1) Randomness

A. Analysis of the randomness of different families of fractures indicates that preferred orientations exist in only a small percentage of the data sets. These are fractures in gneiss, fractures adjacent to faults in the study area, and foliations. Therefore, the character of fracturing has been significantly influenced by regional geologic conditions such as faulting, metamorphism and the juxtaposition of different rock types.

B. The study area was divided into eight regions on the basis of geomorphology. None of the fracture sets in any of the eight regions have preferred orientations at 95 percent confidence. Regions 1 and 5, representing two of the four sharp north to northwest-trending ridges, have preferred orientations at 90 percent confidence. This may be due to topographic sampling bias and/or the uniformity of bedrock characteristics along ridges.

C. The orientation of principal trends of intersection lines between fracture planes in regions 1 through 8 were tested for randomness. All regions except region 7 are non-random at 95 percent confidence.

In summary, although most of the data sets of fractures proved to be randomly distributed at 95 percent confidence, fracture intersections have statistically significant preferred orientations.

## 2) General trends

Contouring sets of poles to fractures shows that the orientations of principal fracture sets in pegmatite are different from fractures in gneiss and amphibolite. The principal strike of fracture sets adjacent to faults is approximately  $40^{\circ}$  from the trend of the faults.

## 3) Regional structural influence

It appears that the distribution of fracture orientations, as observed in outcrops, is mainly derived from late Jurassic through Eocene (Sevier/Laramide)

compression. Rotation of fracture sets to a common horizontal foliation plane suggests that the majority of fractures formed during the earliest stages of Sevier/Laramide compression, and were subsequently contorted by complex folding. Subsequent Miocene through Recent (Basin and Range) extension resulted in further development of the northeast-trending fractures.

#### 4) Controls on fracture characteristics

A comparison of twenty-one data sets grouped by region and by lithology shows that regional location has a significant influence on fracture orientation dispersion parameter  $k$ , while lithology does not. Thus geomorphic environment accounts for a greater variability in fracture orientations than lithology. Geomorphic character is not directly a geological criterion; however, it describes the cumulative expression of an indeterminate combination of physical parameters. From this test it is concluded that the observed fracture geometry of the Farmington Canyon Complex is due to a combination of factors (including lithologic variability and sampling bias) which cannot be resolved separately.

#### 5) Fracture half-length, spacing and intersections

Fracture half-length and spacing distributions appear to be exponential or lognormal, irrespective of lithology or regional position. At one station it was found that longer and more open fractures are similarly oriented to

all the fractures for that station. Based on this example, it was assumed that the theoretical distribution of fracture intersection lines as calculated by the Structure Graphics program is representative of the true distribution of fracture intersection lines in the Farmington Canyon Complex.

#### 6) Geophysical surveys

WADI surveys in Steed and Ford canyons suggested the presence of elongate to linear saturated and unsaturated fracture zones in the bedrock. In the west swale of the Steed Canyon survey, a fracture zone functions as a drain; in the lower Ford Canyon swale, fracture zones appear to be sites of ground water accumulation.

### **Hydrogeology and Application to Slope Failures**

#### 1) The role of fracture intersections

Previous studies have pointed out the importance of fracture interconnectivity in influencing ground-water flow in fractured rock masses (Long and Witherspoon, 1985; Pollard and Aydin, 1988). The distribution of intersection lines for the eight sub-regions in the study area is non-random at 95 percent confidence. However, this study did not find evidence confirming that preferential ground-water flow takes place parallel to the principal trends of fracture intersections. In the absence of such evidence, it is believed that the trends of fracture intersection lines for regions 1, 2, 3, 4, 5,

6 and 8 are the directions of maximum bedrock permeability in these regions.

## 2) Aquifer characteristics

Hydrogeologic evidence suggests that the shallow bedrock forms an aquifer of low specific yield. However, long-term discharge has been observed from some springs and debris flow scars underlain by the Farmington Canyon Complex (Mathewson and Santi, 1987). Therefore, the aquifer is divided into compartments of different sizes. It is believed that faults, fracture zones and/or lithological contacts control the partitioning of the aquifer, by acting either as conduits for deep groundwater flow or as barriers against topographically driven interflow, and thus re-direct ground water obliquely across the slope. The area around the head of Rudd Creek appears to be recharged in this manner (Keaton, 1988a). Further support for this hypothesis is provided by the WADI surveys, which indicated the the presence of water-bearing fractures in the vicinity of a fault in Steed Canyon, and near pegmatite outcrops in Ford Canyon.

## 3) Permeability trends

Two forms of indirect evidence support the hypothesis that ground water travels preferentially along faults. First, a generally northwestward increase in stream discharge (normalized to drainage area) is apparent for five westward-draining canyons in this region. Second,

the greatest number of slope failures within the study area occurred on slopes perpendicular to the principal trend of faults in the study area. No such correlations were found between slope failures and the strikes of fractures or the trends of fracture intersection lines.

The role of steeply-dipping fractures and fracture intersection lines appears to be one of recharge to the deep permeable zones in the bedrock. The extent of communication between shallow structures (fractures and foliation) and deep structures (faults) is important: the greater the permeability of the shallow bedrock, the greater the recharge to the deeper aquifer. Where the fractured shallow bedrock is not near a deep conduit, downslope movement of ground water occurs as interflow, until a permeable zone is encountered, or surface discharge occurs.

#### 4) Surface discharge mechanisms

Bedrock features causing surface discharge of interflow may be relatively less permeable rock bodies such as pegmatite, and/or fracture and foliation sets that intersect the slope, as hypothesized by Mathewson and Santi (1987). A number of gently dipping fractures and foliation planes dip toward the northwest, corresponding to the slopes on which the greatest number of debris flows occurred.

Extrapolating the surficial bedrock structure observed in the study area to all of eastern Davis County, it is concluded that the density of structural discontinuities near the surface is uniformly high. Thus, while the principal trends of discontinuities may vary considerably, overall permeability characteristics of the near-surface bedrock are interpreted to be uniform and nearly isotropic.

Figure 78 A (in pocket) shows the proposed ground-water flow system in the Farmington Canyon Complex between Farmington Canyon and Ward Canyon. Permeability trends in the bedrock between major linears are nearly perpendicular to the linears, allowing for rapid recharge to the deeper flow system. Linears are interpreted to be ground-water conduits. Some, however, may have lower permeability than the material around them, and thus may be barriers to ground-water flow. The barriers that trend across the general westward slope of the Wasatch Front cause ground water to be conducted down and across the slope, parallel to and uphill of the linear feature.

#### **Application to the Debris Flow Hazard**

It is concluded from this study that the distribution of slope failures, particularly debris flows, underlain by the Farmington Canyon Complex is at least partially dependent on bedrock geology. Two general ground-water conditions can lead to a debris flow, consistent with two

different meteorologic conditions. First, intense and localized summer rainstorms may lead to rapid interflow and discharge at contacts with pegmatite, and through low-angle fractures and partings in well-foliated gneisses. Second, spring snowmelt may saturate deep ground-water conduits, causing prolonged discharge and/or slope failure through the localized elevation of pore water pressure in the manner described by Mathewson and Santi (1987).

The results of this study suggest that the future occurrence of slope failures associated with spring snowmelt in this region will take place on slopes perpendicular to regional faults, and at discharge points along fault traces, created by local variations in the permeability of fault zones and the presence of favourably oriented fractures or foliations. Debris flows and shallow landslides associated with intense summer rainfall may correlate more strongly with the occurrence of "daylighting" fractures and foliation, and along contacts between pegmatite and other lithologies.

The proposed distribution of ground-water discharge points and shallow ground water for both of the conditions discussed in the previous paragraph is shown in Figure 78 B (in pocket). Many are located adjacent to creeks, most of which appear to mark the trace of bedrock faults or fracture zones. Thus in the wet season, the entire length of a stream valley becomes a ground-water discharge zone.

In this way, sufficient pore water pressure is maintained along a canyon to allow the continuous mobilization of colluvium in a debris flow, as proposed by Santi (1988).

## RECOMMENDATIONS FOR FURTHER WORK

The traces of regional faults and the trends of lithologic contacts are best identified using aerial photographs. A large percentage of slope failures in this study area correlate with these features. Aerial photograph analysis, with a limited amount of field checking, would provide useful input to slope failure hazard maps of larger regions. Digital image processing would help in identifying these regionally important bedrock features.

The conclusions drawn from the detailed analysis of fracture and foliation orientations may not be directly applicable outside the study area. Because of the heterogeneous geology of the Farmington Canyon Complex, orientations are likely to be quite different elsewhere. In new areas, data collection at the outcrop level may be necessary for comparison with the data sets in this study.

Further work is necessary to test the hypothesized relationship between structural fabric and ground-water flow directions. Useful field techniques might include measuring spring discharge and water chemistry, and conducting tracer tests to investigate the areal extent of aquifer compartments, and travel times.

The relative permeability of gneissic, amphibolitic and pegmatitic rocks should be better established. In

this study, geomorphic and hydrologic evidence was used to infer that pegmatites (at least in the subsurface) are the least permeable rock type.

Slope failure scars in part or all of the study area could be field checked to distinguish those which involved significant deep ground-water discharge from those which may have been initiated by pore water pressures in colluvium or shallow bedrock. This would refine the correlations found in this study between ground-water trends and slope failures.

Finally, the statistical techniques used here for characterizing the dispersion and orientation of families of structural discontinuities can be used in other applications, such as in predicting the fate of solutes in the ground water within fractured rock masses. This is particularly true of regions with less complex fracture geometries. Some preliminary conclusions about the permeability characteristics of a fractured rock mass could be drawn from an analysis of eigenvalues,  $k$ ,  $\alpha_{95}$ , and Kamb contours of fracture poles and intersection lines. The data for these analyses can be gathered relatively quickly. In comparison, in situ hydrogeologic investigations of fractured rock masses can involve very large amounts of money and time; and mathematical treatments are generally extremely complex.

## APPENDIX 1

## TABLE OF NOMENCLATURE

Ma:	Mega-annum (million years)
Ga:	Giga-annum (billion years)
R:	Resultant vector
Ro:	Resultant vector for a random distribution of vector orientations at 95 percent confidence
R:	Magnitude of resultant vector
$S^2$ :	Sum of squares
l:	east direction cosine
m:	north direction cosine
n:	vertical (down) direction cosine
P:	Probability density function describing the Fisher distribution of vectors
K:	Fisher precision parameter; in eigenvalue analysis, an indicator of the shape of the ellipsoid $([S_1/S_2]/[S_2/S_3])$
k:	Estimate of Fisher precision parameter
$\beta$ :	Angular distance between a given data point on a sphere and the spherical mean
$S_1, S_2, S_3$ :	Normalized eigenvalues calculated from sums of products matrix of direction cosines
C:	Strength of the structural fabric, shown by departure from sphericity of the ellipsoid ( $S_1/S_3$ )
n:	Sample population

- alpha95: angular radius of a circle on a sphere which contains 95 percent of the Fisher distributed data
- A: Counting area on lower hemisphere for Kamb contouring
- E: Expected number of observations falling in A
- $\sigma$ : Standard deviation of the number of points that will fall within A for a randomly distributed sample
- $e_p$ : Primary magnetic field emitted by station
- $e_s$ : Secondary field induced by current in subsurface conductor
- $n_j$ : The number of ranked observations in each sample of the Kruskal-Wallis test
- $R_j$ : The numerical value of the summed ranks within each sample of the Kruskal-Wallis test
- q: The summed values of  $(R_j^2/n_j)$  for calculating H
- H: The test statistic for comparison with  $H_0$  and  $H_1$ , calculated as follows:  $H = (12/n[n+1])(q) - 3(n+1)$ ; from Conover, 1980, p. 230.
- $H_0$ : The null hypothesis
- $H_1$ : The alternative ("research") hypothesis

## APPENDIX 2

TABLE OF RESULTANTS (Ro) OF RANDOMLY ORIENTED VECTORS  
AT 95 PERCENT CONFIDENCE

n	0	1	2	3	4	5	6	7	8	9
0	-	-	-	2.62	3.10	3.50	3.85	4.18	4.48	4.76
10	5.03	5.28	5.52	5.75	5.98	6.19	6.40	6.60	6.79	6.98
20	7.17	7.35	7.52	7.69	7.86	8.02	8.18	8.34	8.50	8.65
30	8.80	8.94	9.09	9.23	9.37	9.51	9.65	9.78	9.91	10.0
40	10.2	10.3	10.4	10.6	10.7	10.8	10.9	11.0	11.2	11.2
50	11.4	11.5	11.6	11.7	11.8	11.9	12.0	12.2	12.3	12.4
60	12.5	12.6	12.7	12.8	12.9	13.0	13.1	13.2	13.3	13.4
70	13.5	13.6	13.7	13.8	13.8	13.9	14.0	14.1	14.2	14.3
80	14.4	14.5	14.6	14.7	14.8	14.8	14.9	15.0	15.1	15.2
90	15.3	15.4	15.4	15.5	15.6	15.7	15.8	15.9	15.9	16.0
					100	-	16.1			

Adapted from Irving, 1964. Numbers above 10.0 have been rounded off to one decimal place.

## APPENDIX 3

## KRUSKAL-WALLIS ONE-WAY ANALYSES OF VARIANCE

1) To compare the Fisher k values for different lithologies.

$H_0$  = there is no significant difference in the Fisher k for different lithologies.

$H_1$  = Fisher k values for different lithologies are significantly different.

Confidence level = 95 percent

$n = 21$ ;  $df = 2$

RANKS		
<u>Gneiss</u>	<u>Amphibolite</u>	<u>Pegmatite</u>
5	1	3
6	2	4
7	8	9
12	10	11
13	14	15
18	16	20
21	17	
	19	
$n_j=7$	$n_j=8$	$n_j=6$
$R_j=82$	$R_j=87$	$R_j=62$

Sum from  $j=1$  to  $j=3$  for  $(R_j^2/n_j) = 2547.37 = "q"$ .

$H = (12/n[n+1])(q) - 3(n+1) = 0.165$ .

For small sample sizes, the approximate value of the statistic at 95 percent confidence with  $df=2$  is obtained from the Chi-square distribution. The value of the statistic is 5.991 (Conover, 1980, p. 432); thus  $H_0$  cannot be rejected. It is concluded that the Fisher k values for different lithologies are the same.

2) To compare the Fisher k values for different regions.

$H_0$  = there is no significant difference in the Fisher k for different regions.

$H_1$  = Fisher k values for different regions are significantly different.

Confidence level = 95 percent

$n = 21$ ;  $df = 7$

RANKS OF REGIONS 1-8							
1	2	3	4	5	6	7	8
15	1	3	9	7	11	2	10
19	4	8	12	16	13	6	18
21	5	-	14	-	17	-	20
$n_j=3$	$n_j=3$	$n_j=2$	$n_j=3$	$n_j=2$	$n_j=3$	$n_j=2$	$n_j=3$
$R_j=55$	$R_j=10$	$R_j=11$	$R_j=35$	$R_j=23$	$R_j=41$	$R_j=8$	$R_j=48$

Sum from  $j=1$  to  $j=8$  for  $(R_j^2/n_j) = 3135.20 = "q"$ .

$H = (12/n[n+1])(q) - 3(n+1) = 15.43$ .

The value of the statistic at 95 percent confidence with  $df=7$  is obtained from the Chi-square distribution. The value of the statistic is 14.07 (Conover, 1980, p. 432); thus  $H_0$  is rejected in favour of  $H_1$ . It is concluded that the Fisher k values for different regions are different.

3) To compare alpha95 values for different lithologies.

$H_0$  = there is no significant difference in alpha95 for different lithologies.

$H_1$  = alpha95 values for different lithologies are significantly different.

Confidence level = 95 percent

$n = 21$ ;  $df = 2$

RANKS		
Gneiss	Amphibolite	Pegmatite
1	7	4
2	9	5
3	11	6
10	14	8
11	15	17
13	16	21
19	18	
	20	
$n_j=7$	$n_j=8$	$n_j=6$
$R_j=59$	$R_j=110$	$R_j=61$

Sum from  $j=1$  to  $j=3$  for  $(R_j^2/n_j) = 2629.95 = "q"$ .

$H = (12/n[n+1])(q) - 3(n+1) = 3.03$ .

For small sample sizes, the approximate value of the statistic at 95 percent confidence with  $df=2$  is obtained from the Chi-square distribution. The value of the statistic is 5.991 (Conover, 1980, p. 432); thus  $H_0$  cannot be rejected. It is concluded that alpha95 values for different lithologies are the same.

4) To compare alpha95 values for different regions.

$H_0$  = there is no significant difference in alpha95 for different regions.

$H_1$  = alpha95 values for different regions are significantly different.

Confidence level = 95 percent

$n = 21$ ;  $df = 7$

RANKS OF REGIONS 1-8							
<u>1</u>	<u>2</u>	<u>3</u>	<u>4</u>	<u>5</u>	<u>6</u>	<u>7</u>	<u>8</u>
5	8	6	2	11	3	13	1
9	14	7	4	16	15	18	11
<u>10</u>	<u>19</u>	<u>-</u>	<u>20</u>	<u>-</u>	<u>17</u>	<u>-</u>	<u>21</u>
$n_j=3$	$n_j=3$	$n_j=2$	$n_j=3$	$n_j=2$	$n_j=3$	$n_j=2$	$n_j=3$
$R_j=55$	$R_j=10$	$R_j=11$	$R_j=35$	$R_j=23$	$R_j=41$	$R_j=8$	$R_j=48$

Sum from  $j=1$  to  $j=8$  for  $(R_j^2/n_j) = 2678.40 = "q"$ .

$H = (12/n[n+1])(q) - 3(n+1) = 4.15$ .

The value of the statistic at 95 percent confidence with  $df=7$  is obtained from the Chi-square distribution. The value of the statistic is 14.07 (Conover, 1980, p. 432); thus  $H_0$  cannot be rejected. It is concluded that alpha95 values for different regions are the same.

**APPENDIX 4****ORIGINAL FRACTURE ORIENTATION DATA**

- 1) Raw Data: "Field Observations" and "Wasatch3"
- 2) Reduced Data: "Wholeoutcrop" and "Mean Poles to Bedding"
